New-Street-Square.
PREFACE.

The term Encyclopædia, applied to a single art, is meant to convey the idea of as complete a treatise on that art as can be composed at the time of its publication. No art has been more extended in its objects, or improved in its practices within the last fifty years than Gardening. During that period numerous books have been written in various departments of the subject; but in no work has the whole Art of Gardening been included. The only books which have any pretensions to completeness are the Gardener's Dictionaries: but though some of these are copious on the culture of plants, and others, in botanical description; yet in none is the subject of design, taste, and the arrangement of gardens, adequately treated of; and scarcely any thing is contained in these books, either on the History or Statistics of Gardening. In the voluminous edition of Miller's Dictionary, by Professor Martyn, though the title announces "the addition of all the modern improvements of landscape-gardening," there is not an article bearing that title throughout the work; nor a single quotation or abridgement from the writings of Wheatley, G. Mason, Price, Repton, or any modern author, on the art of laying out grounds.

The Encyclopædia of Gardening now submitted to the public treats of every branch of the Art, and includes every modern improvement to the present year.

Though this work, like every other of the kind, can only be considered as a compilation from books, yet, on various subjects, especially in what relates to Gardening History and Statistics, it was found advisable to correspond with a number of persons both at home and abroad. The favours of these Correspondents are here thankfully acknowledged; and their farther assistance, as well as that of every Reader willing to correct an error or supply a deficiency, is earnestly entreated, in order to render any future edition of the work as perfect as possible.

Besides modern books, it became necessary to consult some comparatively ancient and scarce works only to be met with in particular collections. Our respectful acknowledgments are, on this
account, due to the Council and Secretary of the Linnæan Society; to the Council and Secretary of the Horticultural Society; to Robert Brown, Esq. the possessor of the Banksian library; and to William Forsyth, Esq., whose collection of British works on Gardening is more than usually complete.

It remains only to mention, as a key to this work, that to save room, the prenoms and other additions to names of persons are not inserted; only contracted titles of the books referred to are given; and the names of gardens or country residences are mentioned, without, in many cases, designating their local situation. By turning to the General Index, the names of persons will be found, with the addition of their prenoms and other titles, where known, at length; and there the abridged titles of books are also given complete, and the names of residences, accompanied by that of the county or country in which they are situated. The botanical nomenclature which has been followed is that of Sweet's *Hortus Suburbanus Londinensis*, with only one or two exceptions; the reasons for which are given where they occur. The systematic names of insects, or other animals, or of minerals, are generally those of Linnaeus: some exceptions are also noted. In various parts of the work etymological and other explanations will be found, which, to one class of readers, may be unnecessary. But it is to be considered that we address ourselves to Practical Gardeners as well as to the Patrons of Gardening; and our opinion is, that to enlighten, and generally to raise the intellectual character of the former, will ultimately be found the most efficient mode of improving them in their profession, and thus rendering them more truly valuable to the latter.

By referring to the Kalendarial Index, those parts of this work which treat of Garden Culture and Management may be consulted monthly, as the operations require to be performed; and by recourse to the General Index, the whole may be consulted in detached portions, as in a Dictionary of Gardening.

Although this second edition forms a less bulky volume than the first, yet it contains considerably more printed matter; besides above a hundred new engravings. These important additions we have been enabled to make by printing all those parts of the work which may be considered as of secondary importance, in a smaller type than that of the general text.

J. C. L.

*Bayswater, April 8, 1824.*
CONTENTS.

PART I.
GARDENING CONSIDERED IN RESPECT TO ITS ORIGIN, PROGRESS, AND PRESENT STATE AMONG DIFFERENT NATIONS, GOVERNMENTS, AND CLIMATES.

BOOK I.
HISTORY OF GARDENING AMONG ANCIENT AND MODERN NATIONS.

Chap. I.
Page
Of the Origin and Progress of Gardening in the earliest ages of Antiquity, or from the 4th century before the vulgar era to the foundation of the Roman Empire - 3
I. Of the fabulous Gardens of Antiquity - ib.
II. Jewish Gardens, B.C. 1340 - 4
IV. Babylonian or Assyrian Gardens, B.C. 2000. - 5
V. Persian Gardens, B.C. 500. - 6
VI. Grecian Gardens, B.C. 300. - ib.
VII. Gardening in the ages of Antiquity, as to Fruits, Culinary Productions, and Flowers - 7

Chap. II.
Chronological History of Gardening, from the time of the Roman Kings, in the sixth century B. C. to the Decline and Fall of the Empire in the fifth century of our era - 9
I. Roman Gardening as an Art of Design and Taste - ib.
II. Roman Gardening considered as to the Culture of Flowers and Plants of Ornament - 13
III. Roman Gardening in respect to its Products for the Kitchen and the Dessert - ib.
IV. Roman Gardening considered in respect to the Propagation and Planting of Timber-trees and Hedges - 14
V. Roman Gardening as a Science, and as to the Authors it produced - 15

Chap. III.
Chronological History of Gardening, in continental Europe from the Time of the Romans to the present day, or from A. D. 500 to A. D. 1823. - 16
I. Of the Revival, Progress, and present State of Gardening in Italy - ib.
1. Italian Gardening, in respect to Design and Taste - ib.
2. Italian Gardening in respect to the Culture of Flowers and Plants of Ornament - 21
3. Italian Gardening in respect to its Products for the Kitchen and the Dessert - 23
4. Italian Gardening, in respect to the Planting of Timber-trees and Hedges - 24
5. Italian Gardening, as empirically practised - 25
6. Italian Gardening, as a Science, and as to the Authors it has produced - ib.
II. Of the Revival, Progress, and present State of Gardening in Holland and Flanders - 26
1. Dutch Gardening, as an Art of Design and Taste - ib.
2. Dutch Gardening, in respect to the Culture of Flowers and Plants of Ornament - 29
3. Dutch Gardening in respect to the Culture of Fruits and Culinary Vegetables - 31
4. Dutch Gardening, in respect to the Planting of Timber-trees and Hedges - 31
5. Dutch Gardening, as empirically practised - 32
6. Dutch Gardening, as a Science, and in respect to the Authors it has produced - 33
III. Of the Rise, Progress, and present State of Gardening in France - ib.
1. French Gardening, as an Art of Design and Taste - - ib.
2. French Gardening, in respect to the Culture of Flowers and Plants of Ornament - 39
3. French Gardening, in respect to its Horticultural Productions - 40
4. French Gardening, in respect to the Planting of Timber-trees and Hedges - 41
5. French Gardening, as empirically practised - 42
6. French Gardening, as a Science, and as to the Authors it has produced - 43
IV. Of the Rise, Progress, and present State of Gardening in Germany - ib.
1. German Gardening, as an Art of Design and Taste - - ib.
2. German Gardening, in respect to the Culture of Flowers and Plants of Ornament - 47
3. German Gardening, in respect to Horticultural Productions - 49
4. German Gardening, as to planting Timber-trees and Hedges - 50
5. German Gardening, as empirically practised - - ib.
6. German Gardening, as a Science, and as to the Authors it has produced - 51
V. Of the Rise, Progress, and present State of Gardening in Switzerland - 52
VI. Of the Rise, Progress, and present State of Gardening in Sweden and Norway - 53
VII. Of the Rise, Progress, and present State of Gardening in Russia - 55
1. Russian Gardening, as an Art of Design and Taste - - ib.
2. Russian Gardening, in respect to the Culture of Flowers and Plants of Ornament - 59
3. Russian Gardening, in respect to Horticultural Productions - - ib.
4. Russian Gardening, in respect to the Culture of Timber-trees and Hedges - 60
5. Russian Gardening, as empirically practised - - ib.
6. Russian Gardening, as a Science, and as to the Authors it has produced - 61
VIII. Of the Rise, Progress, and present State of Gardening in Poland - ib.
IX. Of the Rise, Progress, and present State of Gardening in Spain and Portugal - 63
1. Spanish Gardening, as an Art of Design and Taste - - 64
2. Spanish and Portuguese Gardening, in respect to the Culture of Flowers and Plants of Ornament - 65
3. Spanish and Portuguese Gardening, in respect to its Horticultural Productions and Planting - 66
X. Of the Rise, Progress, and present state of Gardening in European Turkey - ib.

### Chap. XI.

**Origin of Culture, as derived from the Study of Vegetables** | 214

## BOOK II.

### OF THE NATURAL AGENTS OF VEGETABLE GROWTH AND CULTURE.

#### Chap. I.

**Of Earths and Soils** | 217

2. Classification and Nomenclature of Soils | 219 |
3. Of discovering the Qualities of Soils by means of the Plants which grow on them | ib. |
4. Of discovering the Qualities of Soils by chemical Analysis | ib. |
5. Of discovering the Qualities of a Soil mechanically and empirically | 220 |
6. Of the Uses of the Soil to Vegetables | 222 |
7. Of the Improvement of Soils | 225 |
8. Of the Improvement of Soils by Compressions | 228 |
9. Of the Improvement of Soils by Aeration or Fallowing | ib. |
10. Of the constituent Parts of Soils | 229 |
11. Changing the Condition of Lands, in respect to Water | 231 |
12. Changing the Condition of Lands, in respect to Atmopheral Influence | 232 |
13. Rotation of Crops | 233 |

#### Chap. II.

**Of Manures** | 234

1. Of Manures of Animal and Vegetable Origin | 235
   2. Of the different Species of Manures of Animal and Vegetable Origin | 236 |
   3. Of the fermenting, preserving, and applying of Manures of Animal and Vegetable Origin | 241 |
2. Of Manures of Mineral Origin | 243
   2. Of the different Species of Mineral Manures | 244 |

#### Chap. III.

**Of the Agency of Heat, Light, Electricity, and Water, in Vegetable Culture** | 249

1. Of Heat and Light | 253 |
2. Of Electricity | ib. |
3. Of Water | ib. |

#### Chap. IV.

**Of the Agency of the Atmosphere in Vegetable Culture** | 254

1. Of the Elements of the Atmosphere | ib. |
2. Of the Means of prognosticating the Weather | 259 |
3. Of the Climate of Britain | 266 |

### BOOK III.

#### Chap. I.

**Implements of Gardening** | 269

1. Tools | ib. |
2. Instruments of Operation | 272 |
3. Instruments of Direction | 276 |
4. Instruments of Designation | 280 |
5. Utensils | 282 |
6. Utensils of Preparation and Deportation | ib. |

### Chap. II.

**Structures used in Gardening** | 298

1. Temporary or Moveable Structures | ib. |
2. Structures Portable or entirely Moveable | ib. |
3. Structures partly Moveable | 300 |
4. Fixed Structures | 303 |
5. Permanent Horticultural Structures | 310
   1. Of the Principles of Design in Hot-houses | 311 |
   2. Of the Forms of Hot-house Roofs | 314 |
   3. Of the Construction of Roofs, or the glazed part of Hot-houses | 318 |
   4. Of Glazing of Hot-house Roofs | 319 |
   5. Of Water-Sheds, and Sheds of Hot-houses | 322 |
   6. Furnaces and Flues | 323 |
   7. Steam Boilers and Tubes | 326 |
   8. Trelis or Trellis-work | 328 |
   9. Paths, Pits, Stages, Shelves, Doors, &c. | 329 |
10. Details of Water, Wind, and Renewal of Air | 331 |
11. Vegetable-houses | 332 |
12. Cold Plant-habitations | 334 |

### Chap. III.

**Edifices used in Gardening** | ib. |

1. Economical Buildings | ib. |
2. Anomalous Buildings | 339 |
3. Of the Ice-house and its Management | ib. |
4. Of the Apiary and the Management of Bees | 341 |
5. Of the Aviary, and of Menageries, Piscinaries, &c. | 346 |
6. Decorative Buildings | 348 |
7. Useful Decorative Buildings | ib. |
8. Convenient Decorations | 355 |
9. Characteristic Decorations | 360 |

### Chap. IV.

**Of the Improvement of the Mechanical Agents of Gardening** | 361

### BOOK IV.

### OF THE OPERATIONS OF GARDENING.

#### Chap. I.

**Operations of Gardening, in which Strength is chiefly required in the Operator** | 353

2. Garden-labors on the Soil | 364 |
3. Garden-labors with Plants | 375 |

#### Chap. II.

**Operations of Gardening in which Skill is more required than Strength** | 359

1. Of transferring Designs from Ground to Paper or Memory | ib. |
2. Of transferring Designs from Paper or Memory to Ground | 373
   1. Transferring Figures and Designs to plane Surfaces | ib. |
   2. Transferring Figures and Designs to irregular Surfaces | 375 |
3. Of the Arrangement of Quantities | 377 |
4. Of carrying Designs into Execution | 375 |

#### Chap. III.

**Scientific Processes and Operations** | 384

1. Preparation of fermenting Substances for Hot-beds, Manures, and Composts | ib. |
2. Operations of Propagation | 387
   1. Preparation by Natural Methods | ib. |
   2. Propagation by Layering | 388 |
   3. Propagation by Inarching | 390 |
   4. Propagation by Grafting | 391 |
   5. Propagation by Budding | 397 |
   6. Propagation by Cuttings | 399
PART III.

GARDENING AS PRACTISED IN BRITAIN.

BOOK I.

HORTICULTURE.

CHAP. I.

The Formation of a Kitchen-garden

1. Situation
2. Exposure and Aspect
3. Extent
4. Shelter and Shade
5. Soil
6. Water
7. Forage
8. Walls
9. Ring-fence and Slip
10. Laying out the Area

CHAP. II.

Of the Distribution of Fruit-trees in a Kitchen-garden

1. Of the Selection and Arrangement of Fruit-trees
2. Of the Selection and Arrangement of Espaliers and Dwarf-standards
3. Of tall Standard Fruit-trees in a Kitchen-garden
4. Fruit-shrubs

CHAP. III.

Of the Formation and Planting of an Orchard, subsidiary to the Kitchen-garden

CHAP. IV.

Of the general Cultivation and Management of a Kitchen-garden

1. Culture and Management of the Soil
2. Manure
3. Cropping
4. Thinning
5. Pruning and Training
6. Weed-ling, Stirring the Soil, Protecting, Supporting, and Shading
7. Watering
8. Vermin, Insects, Diseases, and Accidents
9. Gathering and Preserving Vegetables and Fruits, and sending them to a Distance
10. Miscellaneous Operations of Culture and Management

CHAP. V.

Of the general Management of Orchards

1. General Culture
2. Pruning Orchard-trees
3. Of gathering and storing Orchard-fruits
4. Of packing Orchard and other Fruits for Carriage

CHAP. VI.

Construction of the Culinary Forcing Structures and Hot-houses
CONTENTS.

8. Of Insects which infest the Cabbage Tribe 617
11. Leguminous Plants 618
2. Garden-bean 620
3. Kidneybean 621

III. Excellent Roots
1. Potatoe 623
2. Jerusalem Artichoke 623
3. Turnip 623
4. Carrot 624
5. Parsnip 624
6. Red Beet 624
7. Skirret 628
8. Scorzonera, or Viper's Grass 628
9. Salsify, or Purple Go'd's Beard 628
10. Radish 628

IV. Spinaceous Plants
1. Spinage 630
2. White Beet 630
3. Orache, or Mountain Spinage 630
4. Wild Spinage 630
5. New Zealand Spinage 630
6. Sorrel 630

VII. Herb-patience, or Patience-Dock 639

V. Allaceous Plants
1. Onion 640
2. Leek 640
3. Chive 642
4. Garlic 642
5. Shallot 642
6. Rocambole 643

VI. Asparagus Plants 644
1. Asparagus 644
2. Sea-kale 645
3. Artichoke 645
4. Ceps or Clorhond 645
5. Rampion 645
6. Hop 645
7. Ailender, or Alexander 645
8. Blanket-Campion 645
9. Thistle 645

VII. Acetarious Plants
1. Lettuce 650
2. Endive 650
3. Succory, or Wild Endive 650
4. Dandelion 650
5. Celery 650
6. Mustard 650
7. Rape 650
8. Corn-Salad, or Lamb-Lettuce 650
9. Garden-Cress 651
10. American Cress 651
11. Winter Cress 652
12. Water-Cress 652
13. Brook-lime 652
14. Garden-rocket 652
15. Scoury-grass 652
16. Butlet 652
17. Wood Sorrel 654
18. Small Salads 654

VIII. Pot-herbs and Garnishings
1. Parsley 655
2. Purslane 655
3. Tarragon 655
4. Watercress 655
5. Dill 656
6. Chervil 656
7. Horse-radish 656
8. Indian Cress, or Nasturtium 657
9. Marigold, or Pot-marigold 657
10. Borage 658

IX. Sweet Herbs
1. Thyme 660
2. Sage 660
3. Clary 660
4. Mint 660
5. Marjoram 660
6. Savory 660
7. Basil 661
8. Rosemary 661
9. Lavender 661
10. Tansy 661
11. Costmary, or Alecost 663

X. Plants used in Tarts, Confectionary, and Domestic Medicine
1. Rhubarb 671
2. Pompon and Gourd 671
3. Angelica 676
4. Anise 676
5. Coriander 676
6. Caraway 676
7. Rue 671

XI. Plants used as Preserves and Pickles
1. Love-Apple 679
2. Egg-plant 679
3. Capsicum 680
4. Samphire, three Species of different Order and Genera 680
5. Wild Plants applied to various Domestic Purposes 680
7. Poisonous Native Plants to be avoided in searching for edible Wild Plants 684

XII. Edible Wild Plants, neglected, or not in Culture
1. Greens and Pot-herbs from Wild Plants 681
2. Roots of Wild Plants edible 681
3. Leguminous Wild Plants edible 683
4. Salads from Wild Plants 683
5. Substitutes for Chinese Teas from Wild Plants 683

XIII. Foreign hardy herbaceous Culinary Vegetables, little used as such in Britain 684

XIV. Edible Fungi
1. Cultivated Mushroom 685
2. Morel 685
3. Truffle, or Subterraneous Puff-ball 685

XV. Edible Fuci

Chap. IX.
Horticultural Catalogue. — Hard Fruit-trees, Shrubs, and Plants 687

KALENDARIAL INDEX - - - 1147

GENERAL INDEX - - - 1165
THE earth, Herder observes, is a star among other stars, and man, an improving animal acclimated in every zone of its diversified surface. The great mass of this star is composed of inorganic matters called minerals, from the decomposing surface of which proceed fixed organic bodies called vegetables, and moving organic bodies called animals. Minerals are said to grow, or undergo change only; vegetables to grow and live; and animals to grow, live, and move. Life and growth imply nourishment; and primitively, vegetables seem to have lived on minerals; and animals, with some exceptions, on vegetables. Man, supereminent, lives on both; and, in consequence of his faculty of improving himself and other beings, has contrived menus of increasing the number, and ameliorating the quality of those he prefers. This constitutes the chief business of private life in the country, and includes the occupations of housewifery, or domestic economy, agriculture, and gardening.

Gardening, the branch to which we here confine ourselves, as compared with agriculture, is the cultivation of a limited spot, by manual labor, for culinary and ornamental products; but relative to the present improved state of the art, may be defined the formation and culture, by manual labor, of a scene more or less extended, for various purposes of utility, ornament and recreation.

Thus gardening, like most other arts, has had its origin in the supply of a primitive want; and, as wants became desires, and desires increased, and became more luxurious and refined, its objects and its province became extended; till from an enclosure of a few square yards, containing, as Lord Walpole has said, "a gooseberry-bush and a cabbage," such as may be seen before the door of a hut on the borders of a common, it has expanded to a park of several miles in circuit, its boundaries lost in forest scenery,—a palace bosomed in wood near its centre; the intermediate space varied by artificial lakes or rivers, plantations, pleasure-grounds, flower-gardens, hot-houses, orchards, and potageries:—producing for the table of the owner and his guests, the fruits, flowers, and culinary vegetables, of every climate of the world!—displaying the finest verdant landscapes to invite him to exercise and recreation, by gliding over velvet turf, or polished gravel walks, sheltered, shady, or open in near scenes; or with horses and chariots along rides and drives "of various view" in distant ones.

From such a variety of products and objects, and so extended a scene of operations, have arisen the different branches of gardening as an art; and from the general use of gardens, and of their products by all ranks, have originated their various kinds, and the different forms which this art has assumed as a trade or business of life. Gardening is practised for private use and enjoyment, in cottage, villa, and mansion gardens;—for public recreation, in umbrageous and verdant promenades, parks, and other scenes, in and near to large towns;—for public instruction, in botanic and experimental gardens;—for public example, in national or royal gardens;—and for the purpose of commerce, in market, orchard, seed, physic, florists', and nursery gardens.

To aid in what relates to designing and laying out gardens, artists or professors have arisen; and the performance of the operative part is the only source of living of a numerous class of serving gardeners, who acquire their art by the regular routine of apprenticeship, and probationary labor for some years as journeymen.
The products of the kitchen-garden form important articles of human food for all ranks of society; and furnish the chief luxuries of the tables of the rich, and a main support of the families of the poor. One of the first objects of a colonist on arriving at a new settlement is to plant a garden, as at once a proof of possession, and a pledge of immediate enjoyment; and indeed the history of the civilisation of mankind bears evidence, that there are few benefits which a cultivated people can bestow on savage tribes, greater than that of distributing among them the seeds of good fruits and oleaceous herbs, and teaching them their culture.

The pleasure attending the pursuit of gardening is conducive to health and repose of mind; and a taste for the enjoyment of gardens is so natural to man, as almost to be universal. Our first most endearing and most sacred associations, Mrs. Hoftland observes, are connected with gardens; our most simple and most refined perceptions of beauty are combined with them; and the very condition of our being compels us to the cares, and rewards us with the pleasures attached to them. Gardening has been the inclination of kings and the choice of philosophers, Sir William Temple has observed; and the Prince de Ligne, after sixty years' experience, affirms, that the love of gardens is the only passion which augments with age: "Je voudrois," he says, "échauffer tout l'univers de mon gout pour les jardins. Il me semble qu'il est impossible, qu'un médecin puisse l'avoir. Il n'est point de vertus que je ne supposer à celui qui aime à parler et à faire des jardins. Pères de famille, inspirez la jardinoanerie à vos enfants." (Mémoires et Lettres, tom. i.)

That which makes the cares of gardening more necessary, or at least more excusable, the former author adds, is, that all men eat fruit that can get it; so that the choice is only, whether one will eat good or ill; and for all things produced in a garden, whether of salads or fruits, a poor man will eat better that has one of his own, than a rich man that has none.

To add to the value and extend the variety of garden productions, new vegetables have been introduced from every quarter of the globe; to diffuse instruction on the subject, numerous books have been written, societies have been established, and premiums held out for rewarding individual merit; and where professors of rural economy exist, gardening may be said to form a part of public instruction.

A varied and voluminous mass of knowledge has thus accumulated on the subject of gardening, which must be more or less necessary for every one who would practise the art with success, or understand when it is well practised for him by others. To combine as far as practicable the whole of this knowledge, and arrange it in a systematic form, adapted both for study and reference, is the object of the present work. The sources from which we have selected, are the modern British authors of decided reputation and merit; sometimes recurring to ancient or continental authors, and occasionally, though rarely, to our own observation and experience; — observation in all the departments of gardening, chiefly in Britain, but partly also on the Continent; and experience during nearly twenty years' practice as an architect of gardens.

With this purpose in view, Gardening is here considered, in

---|---
I. As to its origin, progress, and present state, | 1. Among the different nations of the world.
 | 2. Under different political and geographical circumstances.
II. As a science founded on - | 1. The study of the vegetable kingdom.
 | 2. The study of the natural agents of vegetable growth and culture.
 | 3. The study of the mechanical agents employed in gardening.
 | 4. The study of the operations of gardening.
III. As an art, comprehending | 1. The practice of horticulture.
 | 2. The practice of floriculture.
 | 3. The practice of arboreulture.
 | 4. The practice of landscape gardening.
IV. Statistically in Britain - | 1. As to its present state.
 | 2. As to its future progress.

A Kalendarial Index to those parts of the work which treat of culture and management, points out the operations as they are to be performed in the order of time and of the season: and

A General Index explains the technical terms of gardening; gives an outline of the culture of every genus of plants, native or introduced in British gardens; and presents an analysis of the whole work in alphabetical order.
PART I.

GARDENING CONSIDERED IN RESPECT TO ITS ORIGIN, PROGRESS, AND PRESENT STATE AMONG DIFFERENT NATIONS, GOVERNMENTS, AND CLIMATES.

1. The history of gardening may be considered chronologically, or in connection with that of the different nations who have successively flourished in different parts of the world; politically, as influenced by the different forms of government which have prevailed; and geographically, as affected by the different climates and natural situations of the globe. The first kind of history is useful as showing what has been done; and what is the relative situation of different countries as to gardens and gardening; and the political and geographical history of this art affords interesting matter of instruction as to its past and future progress.

BOOK I.

HISTORY OF GARDENING AMONG ANCIENT AND MODERN NATIONS.

2. The chronological history of gardening may be divided into three periods; the ages of antiquity, commencing with the earliest accounts and terminating with the foundation of the Roman empire; the ancient ages, including the rise and fall of the Roman empire; and the modern times, continued from thence to the present day.

CHAP. I.

Of the Origin and Progress of Gardening in the earliest ages of Antiquity, or from the 10th century before the vulgar era to the foundation of the Roman Empire.

3. All ancient history begins with fable and tradition; no authentic relation can reach farther back than the organisation of the people who followed the last grand revolution sustained by our globe. Everything which pretends to go farther must be fabulous, and it is only the primeval arts of war and husbandry which can by any means go so far. The traditions collected by Herodotus, Diodorus, Hesiod, and some other authors, when freed from the mythological and mysterious terms in which they are enveloped, seem to carry us back to that general deluge, or derangement of the surface strata of our globe, of which all countries, as well as most traditions, bear evidence. As to gardening, these traditions, like all rude histories, touch chiefly on particulars calculated to excite wonder or surprise in ignorant or rude minds, and accordingly the earliest notices of gardens are confined to fabulous creations of fancy, or the alleged productions of princes and warriors. To the first may be referred the gardens of Paradise and the Hesperides; and to the others the gardens of the Jews, Babylonians, Persians, and Greeks.

SECT. I. Of the fabulous Gardens of Antiquity.

4. The fabulous gardens of antiquity are connected with the religions of those times. These religions have been arranged by philosophers (De Pau's Dissert.) in three divisions; Barbarism, Scythism, and Helenism. To the latter belong the Hebrew, Greek, and Mahomedan species. Each of these has its system of creation, its heaven and its hell, and, what chiefly concerns us, each system has its garden. The garden of the Jewish mythology is for the use of man; that of the Grecian polytheism is appropriated to the Gods; and the Mahomedan paradise is the reward held out to the good in a future state.

5. Gan-eden, or the Jewish Paradise, is supposed to have been situated in Persia, though the inhabitants of Ceylon say it was placed in their country, and according to the Rev. Dr. Buchanan (Researches in India, &c.), still point out Adam's bridge and Abel's tomb. Its description may be considered as exhibiting the ideas of a poet, whose object was to bring together every sort of excellence of which he deemed a garden susceptible; and it is remarkable that in so remote an age (B.C. 1600) his picture should display so much of general nature. Of great extent, watered by a river, and abounding in timber and woodiness, paradise seems to have borne some resemblance to a park and pleasure-gounds in the modern taste; to which indeed its amplified picture by Milton has been thought by Walpole and others to have given rise. When Adam began to transgress in
the garden he was turned out to till the ground, and paradise was afterwards guarded by a miraculous sword, which turned every way to meet trespassers. (See Genesis ii. 3.; Bishop Huet on the Situation of Paradise, 1691, 12mo.; Burnet's Theory of the Earth, book ii. chap. 2.; Sickler's Geschichte der obst cultur, &c. 1801. 1 Band.)

6. The gardens of Hesperides were situated in Africa, near Mount Atlas, or, according to some, near Cyreneaca. They are described by Seylax, a geographer of the sixth century, B. C., as lying in a place eighteen fathoms deep, steep on all sides, and two stadia in diameter, covered with trees of various kinds, planted very close together, and interwoven with one another. Among the fruit-trees were golden apples (supposed to be oranges), pomegranates, mulberries, vines, olives, almonds, and walnuts; and the ornamental trees included the arbutus, myrtle, bay, ivy, and wild olive. This garden contained the golden apples which Juno gave to Jupiter on the day of their nuptials. They were occupied by three celebrated nymphs, daughters of Hesperus, and guarded by a dreadful dragon which never slept. Hercules carried off the apples by stratagem, but they were afterwards returned by Minerva. What finally became of the nymphae of the garden, or of the apples, we are as ignorant as we are of the fate of paradise, or the tree "in the midst thereof," which contained the forbidden fruit, and of which, as Lord Walpole observes, "not a slip or a sucker has been left behind."

7. The promised garden of Mahomet, or the heaven of his religion, is said to abound in unbragious groves, fountains, and Houri, or black-eyed girls: and the enjoyments, which in such scenes on earth last but for a moment, are to be there prolonged for a thousand years.

8. Dr. Sickler's opinion of these gardens is, that Eden and Hesperides allude to, or are derived from, one original tradition. Paradise, he considers as a sort of figurative description of the finest district of Persia; and he traces various resemblances between the apples of Eve and of Juno; the dragon which never slept, and the flaming sword which turned every way. Some very learned and curious speculations on this subject are to be found in the introduction to his Geschichte der obst cultur. With respect to the paradise of Mahomet, it is but of modern date, and may probably have been suggested by the gardens described in "Solomon's Song," and other poems; though some allege that the rural coffee-houses which abound in the suburbs of Constantinople gave the first idea to the prophet.

Sect. II. Jewish Gardens. B. C. 1500.

9. King Solomon's garden is the principal one on record; though many others belonging both to Jewish princes and subjects are mentioned in the Bible. Solomon was at once a botanist, a man of learning, of pleasure, and a king. The area of his garden was quadrangular, and surrounded by a high wall; it contained a variety of plants, curious as objects of natural history, as the hyssop, (a moss, as Hasselquist thinks,) "which springeth out of the wall;" odoriferous and showy flowers, as the rose, and the lily of the valley, the calamus, camphire, spikenard, saffron, and cinnamon; timber-trees, as the cedar, the pine, and the fir; and the richest fruits, as the fig, grape, apple, palm, and pomegranate. (Curtii Sprengel Historia Rei herbatariae, lib. i. c. 1.) It contained water in wells, and in living streams, and, agreeably to eastern practices, aviaries and a seraglio. The seraglio Parkhurst supposes was at once a temple of worship and of pleasure, and he quotes the words of Ezekiel (xiii. 20.) in their literal translation: "I am against, saith the Lord, your luxurious cushions, wherewith ye ensnare souls in the flower-gardens." Ashuè or Venus was the deity who was worshipped by a company of naked females: Dr. Brown (Antiq. of the Jews,) describes the mode of worship; and concludes by lamenting that depravity in man, which converts the beauties of nature into instruments of sin. The situation of Solomon's garden was in all probability near to the palace, as were those of his successors, Ahasuerus and Ahab. (Esther vii. 8.)

10. We know little of the horticulture of the Jews; but like that of the eastern nations in general, it was probably then as it is still in Canaan, directed to the growing of cooling fruits, to allay thirst and moderate heat; aromatic herbs to give a tone to the stomach, and wine to refresh and invigorate the spirits. Hence, while their agricultural produce was wheat, barley, rye, millet, vetches, lentils, and beans, their gardens produced cucumbers, melons, gourds, onions, garlic, anise, cummin, coriander, mustard, and various spices. Their vineyards were sometimes extensive: Solomon had one at Baalhamon which he let out at 1000 pieces of silver per annum. (Cant. viii. 11, 12.)

11. The garden of Alcinous, the Phaeacian king, was situated in an island of that name, by some considered Corfu, in the Ionian sea, and by others, and with more reason, an Asiatic island. It is minutely described by Homer in the Odyssey, and may be compared to the garden of an ordinary farm-house in point of extent and form; but in respect to the variety of fruits, vegetables, and flowers cultivated, was far inferior. It
embraced the front of the palace; contained something less than four acres, surrounded by a hedge, (the first, as Harte remarks, which we read of in history,) and interspersed with three or four sorts of fruit-trees, some beds of culinary vegetables, and some borders of flowers; it contained two fountains or wells, the one for the use of the garden, and the other for the palace.

12. The gardens of Laertes, described in the same work, appear to have been similar to the above in character and extent, use being more studied than beauty; and vicinity to the house or palace, for the immediate access of the queen or housewife, being a greater desideratum than extent, variety of products, or prolonged recreation.

13. The reality of the existence of these gardens is very doubtful. They are by many ranked with those of Adonis (Virg. Georg. ii. 87.), Paradise, Hesperides (Virg. Æn. iv. 484.), and Venus (Ali Bey's Travels, vol. i.), and considered with them as mere creations of the fancy. Sir W. Temple is of opinion that the principal gardens of Ionia may have had some resemblance to those described by Homer, as lying in the barren island of Phaeacia; but that the particular instance stated as belonging to Alcinous is wholly poetical. (Temple's Works. Essay on Gardens.) Gouget rejects altogether the idea of Phaeacia being an European isle, and considers the Phaeacians as a Greek colony in one of the islands of Asia. (Origine de Loiz, &c. tom. iii. 174.)

SECT. IV. Babylonian or Assyrian Gardens. B. C. 2000.

14. The gardens of Cyrus at Babylon (Plin. xix. 4.), or of the kings of Assyria, or, according to Bryant (Anal. of Ancient Mythology, vol. iii. p. 100.), of the chiefs of the ancient people called Semarim, were distinguished by their romantic situations, great extent, and diversity of uses and products, and were reckoned in their days among the wonders of the world.

15. The form of these gardens was square, and, according to Diodorus and Strabo, each side was four hundred feet in length, so that the area of the base was nearly four acres. They were made to rise with terraces constructed in a curious manner above one another, in the form of steps, somewhat like those of the Isola Bella in the Lago Maggiore in Italy, and supported by stone pillars to the height of more than three hundred feet, gradually diminishing upwards till the area of the superior surface, which was flat, was reduced considerably below that of the base. This building was constructed by vast stone beams placed on pillars of stone, (arches not being then invented,) which were again covered with reeds, cemented with bitumen, and next were laid a double row of bricks united by cement. Over these were laid plates of lead, which effectually prevented the moisture from penetrating downwards. Above all was laid a coat of earth, of depth sufficient for plants to grow in it, and the trees here planted were of various kinds, and were ranged in rows on the side of the ascent, as well as on the top, so that at a distance it appeared as an immense pyramid covered with wood. The situation of this extraordinary effort was adjoining or upon the river Euphrates, from which water was supplied by machinery for the fountains and other sources for cooling the air and watering the garden. (Dr. Falconer's Historical View of the Gardens of Antiquity, &c. p. 17.)

16. The prospect from these elevated gardens was grand and delightful. From the upper area was obtained a view not only of the whole city, and the windings of the Euphrates, which washed the base of the superstructure three hundred feet below; but of the cultivated environs of the city and surrounding desert, extending as far as the eye could reach. The different terraces and groves contained fountains, parterres, seats and banquetting-rooms, and combined the minute beauties of flowers and foliage, with masses of shade and extensive prospects;—the retirement of the grove in the midst of civic mirth and din;—and all the splendor and luxury of eastern magnificence in art, with the simple pleasures of verdant and beautiful nature. "This surprising and laborious experiment," G. Mason observes, "was a strain of complaisance in King Nebuchadnezzar to his Median queen, who could never be reconciled to the flat and naked appearance of the province of Babylon, but frequently regretted each rising hill and scattered forest she had formerly delighted in, with all the charms they had presented to her youthful imagination. The King, who thought nothing impossible for his power to execute, nothing to be unattempted for the gratification of his beloved consort, determined to raise woods and terraces even within the precincts of the city, equal to those by which her native country was diversified." (Essay on Design, &c. p. 9.)

17. An elevated situation seems in these countries to have been an essential requisite to a royal garden; probably because the air in such regions is more cool and salubrious,—the security from hostile attack of any sort more certain,—and the prospect always sublime. "When Semiramis came to Chanon, a city of Media," observes Diodorus Siculus (lib. ii. cap. 13.), "she discovered on an elevated plain, a rock of stupendous height, and of considerable extent. Here she formed another paradise, exceeding large, enclosing a rock in the midst of it, on which she erected sumptuous buildings for pleasure, commanding a view both of the plantations and the encampment."
HISTORY OF GARDENING.

Part I.

18. The existence of these gardens, however, is very problematical. Bryant (Ancient Mythology) gives his reasons for disbelieving the very existence of Queen Semiramis, who, Dr. Sickler says, was not a queen, but a (beyachlawferian) concubine. Bryant acknowledges, however, that paradises of great extent, and placed in elevated situations, were with great probability ascribed to the ancient people called Semarin. Quintus Curtius (lib. xv. cap. 5.) calls these gardens "fabulous wonders of the Greeks:" and Herodotus, who describes Babylon, is silent as to their existence. Many consider their description as representing a hill cut into terraces, and planted; and some modern travellers have fancied that they could discover traces of such a work. The value of such conjectures is left to be estimated by the antiquarian; we consider the description of this Babylonian garden as worth preserving for its grandeur and suitableness to the country and climate.

19. The Persian Kings were very fond of gardens, which, Xenophon says, were cultivated for the sake of beauty as well as fruit. "Wherever the Persian king, Cyrus, resides, or whatever place he visits in his dominions, he takes care that the Paradises, shall be filled with every thing, both beautiful and useful, the soil can produce." (Xen. Memorab. lib. v. p. 829.) The younger Cyrus was found by Ly- sander, as Plutarch informs us, in his garden or paradise at Sardis, and on its being praised by the Spartan general, he avowed that he had conceived, disposed and adjusted the whole himself, and planted a considerable number of trees with his own hands. Cyrus had another paradise at Celenze, which was very extensive, and abounded in wild beasts; and we are informed that the same prince "there mustered the Grecian forces to the number of thirteen thousand." (De Cyri Esped. lib. i.)

20. A paradise in the Island of Panchaea, near the coast of Arabia, is described by Diodorus Siculus, as having been in a flourishing state in the time of Alexander's immediate successors, or about B. C. 300. It belonged to a temple of Jupiter Try- philius, and had a copious fountain, which burst at once into a river, was cased with stone near half a mile, and was afterwards used for irrigation. It had the usual accom- paniments of grooves, fruit-trees, thickets, and flowers.

21. The grove of Orontes in Syria, is mentioned by Strabo (lib. xvi.) as being in his time nine miles in circumference. It is described by Gibbon as "composed of laurels and cypress, which formed in the most sultry summers a cool and impenetrable shade. A thousand streams of the purest water issuing from every hill preserved the verdure of the earth, and the temperature of the air; the senses were gratified with harmonious sounds, and aromatic odours; and the peaceful grove was consecrated to health and joy, to luxury and love." (Decline and Fall of the Roman Empire, chap. xiii.)

22. In Persian gardens of a more limited description, according to Pliny and other Ro- man authors, the trees were arranged in straight lines and regular figures; and the margins of the walks covered with tufts of roses, violets, and other odoriferous flowering plants. Among the trees, the terebinthinate sorts, the oriental plane, and, what may appear to us remarkable, the narrow-leaved elm, (now called English, but originally, as Dr. Walker and others consider, from the Holy Land), held conspicuous places. Buildings for repose, banquetting, voluptuous love; fountains for cooling the air, aviaries for choice birds, and towers for the sake of distant prospect, were introduced in the best examples.

Sect. VI. Grecian Gardens. B. C. 300.

23. The Greeks copied the gardening of the Persians, as they did their manners and architecture, as far as the difference of climate and state of society would admit. Xenophon, a Greek philosopher of the fourth century before Christ, admired the gardens of the Persian prince Cyrus, at Sardis; and Diogenes Laertius informs us that Epicurus delighted in the pleasures of the garden, and made choice of one as the spot where he taught his philosophy. Plato also lays the scene of his dialogue of beauty on the unbragious banks of the river Iliusus. In the first eneoglogue of Theocritus, the scene is laid under the shade of a pine-tree, and the beauty of Helen is compared to that of a cypress in a garden. It would appear from this and other circumstances, that the love of terebinthinate trees, so general in Persia, and the beauty of Helen is compared to that of a cypress in a garden. It would appear from this and other circumstances, that the love of terebinthinate trees, so general in Persia, and the beauty of Helen is compared to that of a cypress in a garden. It would appear from this and other circumstances, that the love of terebinthinate trees, so general in Persia, and the beauty of Helen is compared to that of a cypress in a garden. It would appear from this and other circumstances, that the love of terebinthinate trees, so general in Persia, and the beauty of Helen is compared to that of a cypress in a garden. It would appear from this and other circumstances, that the love of terebinthinate trees, so general in Persia, and the beauty of Helen is compared to that of a cypress in a garden.
24. The vale of Tempe, however, as described in the third book of Ælian's various history, and the public gardens of Athens according to Plutarch, prove that their philosophers and great men were alive to the beauties of verdant scenery. The academus or public garden of Athens, Plutarch informs us, was originally a rough uncultivated spot, till planted by the general Cinon, who conveyed streams of water to it, and laid it out in shady groves, with gymasia, or places of exercise, and philosophic walks. Among the trees were the olive, plane, and elm; and the two last sorts had attained to such extraordinary size, that at the siege of Athens by Sylla, in the war with Mithridates, they were selected to be cut down, to supply warlike engines. In the account of these gardens by Pausanias we learn, that they were highly elegant, and decorated with temples, altars, tombs, statues, monuments, and towers; that among the tombs were those of Pirithous, Theseus, Æolipus, and Adrastus; and at the entrance was the first altar dedicated to love.

25. The passages of the Greek writers which relate to gardens have been amply illustrated by the learned German antiquarian Bättinger (Racemationen zur Gartenkunst der Alten); on which it may be remarked, that the qualities chiefly enlarged on are, shade, coolness, freshness, breezes, fragrance, and repose — effects of gardening which are felt and relished at an earlier period of human civilisation than picturesque beauty, or other poetical and comparatively artificial associations with external scenery; for though gardening as a merely useful art may claim priority to every other, yet as an art of imagination, it is one of the last which has been brought to perfection. In fact, its existence as such an art, depends on the previous existence of pastoral poetry and mental cultivation; for what is nature to an uncultivated mind?

Sect. VII. Gardening in the ages of Antiquity, as to Fruits, Culinary Productions, and Flowers.

26. The first vegetable production which attracted man's attention as an article of food, is supposed to have been the fruit of some tree; and the idea of removing such a tree to a spot, and enclosing and cultivating it near his habitation, is thought to be abundantly natural to man, and to have first given rise to gardens. All the writers of antiquity agree in putting the fig at the head of the fruit-trees that were first cultivated. The vine is the next in order, the fruit of which serves not only for food, like that of the fig, but also for drink. Noah the Jewish Bacchus, and Osiris the Bacchus of the Egyptians and Greeks, are alike placed in the very first age of the postdiluvian world. The almond and pomegranate were early cultivated in Canaan (Gen. xliii. 5. 11. and Num. xx. 5.), and it appears by the complaints of the Israelites in the wilderness, that the fig, grape, pomegranate, and melon, were known in Egypt from time immemorial.

27. The first herbage made use of by man, would be the most succulent leaves or stalks which the surface around him afforded; of these every country has some plants which are succulent even in a wild state, as the chenopod. Sea cale, and asparagus, were known to the Greeks from the earliest ages, and still abound in Greece, the former on the sandy plains, and the latter on the sea shores. One of the laws of Solon prohibits women from eating crambe in child-bed. Of the green seeds of herbage plants, the bean and other leguminosee were evidently the first in use, and it is singular that Pythagoras should have forbidden the use of beans to his pupils because they were so much of the nature of flesh; or, in the language of modern chemistry, because they contained so much vegeto-animal matter.

28. The first roots, or rootlike parts of plants made use of, must have been some of the surface bulbs, as the onion, (Numb. xi. 5.) and the edible crocus (C. arveus, Fl. Grec.) of Syria. Underground bulbs and tubers, as the orchis, potato, and earthnut, would be next discovered; and ramose roots, as those of the lucerne in Persia, and arracacha (Leguminosae sp. ?) in Mexico, would be eagerly gnawed wherever they could be got at. Bulbs of culture, as the turnip, would be of much later discovery, and must at first have been found only in temperate climates.

29. The use of plants for preternatural, religious, funereal, medical, and scientific purposes, like every other use, is of the remotest antiquity. Rachel demanded from her sister the mandrakes (Mandragora officinalis, W.) (fig. 1. from the Flora Graeca), whose roots are thought to resemble the human form, which Reuben had brought from the fields; impressed, as she no doubt was, with the idea of the efficacy of that plant against sterility. Bundles of flowers covered the tables of the Greeks, and were worn during repasts, because the plants, of which they consisted, were supposed to possess the virtue of preserving the wearer from the fumes of wine, of refreshing the thinking faculty, preserving the purity of ideas, and the gaiety of the spirits. Altars were strewn with flowers both by Jews and Greeks; they were placed on high places, and under trees, as old clothes are still sacrificed on the trunks of the Planeus in Georgia and Persia. God appeared to Moses in a bush. Jacob was embalmed, in all probability, with aromatic herbs.
Aristotle's materia medica was chiefly plants. Solomon wrote on botany as a philosopher, and appears to have cultivated a general collection, independently of his plants of ornament.

30. Flowers, as decorations, must have been very soon used on account of their brilliant colors and smell. The Greeks, Theophrastus informs us, (Hist. Plant. lib. vi. c. 5.), cultivated roses, gilly-flowers, violets, narcissi, and the iris; and we read in Aristophanes (Acharn. v. 212.), that a market for flowers was held at Athens, where the baskets were very quickly disposed of. From the writings of other authors, we learn that a continual use was made of flowers throughout all Greece. Not only were they then, as now, the ornament of beauty, and of the altars of the gods, but youth crowned themselves with them in the fêtes: priests in religious ceremonies; and guests in convivial meetings. Garlands of flowers were suspended from the gates in times of rejoicing; and, what is still more remarkable, and more remote from our manners, the philosophers themselves wore crowns of flowers, and the warriors ornamented their foreheads with them in days of triumph. These customs existed in every part of the East. There were at Athens, as afterwards at Rome, florists, whose business it was to weave crowns (coronaria) and wreaths of flowers. Some of these crowns and garlands were of one species of flower; others of different species; or of branches of peculiar plants, relating to some symbolic or mythological idea. Hence the term, coronariae, was applied to such plants as were consecrated to those uses, and of which some were cultivated, and others gathered in the fields; but the name was applied to all such as were distinguished by the beauty or fragrance of their flowers. (Curt. Spreng. Hist. R. Herb. lib. i. & ii.; Paschalis de Coronis, lib. x.; Sabina by Bettinger, in N. Mon. Mag. Jan. and Feb. 1819.; Theophrastus by Stackhouse, &c.)

31. The first implement used in cultivating the soil, all antiquarians agree, must have been of the pick kind. A medal of the greatest antiquity, dug up in the island of Syracuse, contained the impression of such an implement (Fig. 2. a). Some of the oldest Egyptian hieroglyphics have similar representations (b); and Eckeburg has figured what may be considered as the primitive spade of China (c). In the beginning of the sixteenth century, when Peru was discovered by the Spaniards, the gardeners of that country had no other spade than a pointed stick, of which the more industrious made use of two at a time. (d) The Chinese implement bears the highest marks of civilisation, since it has a hilt or cross handle, and a tread for the foot; and consequently supposes the use of shoes or sandals by the operator, and an erect position of his body. The Roman spade (tigo), those of Italy (zappa), and of France (bêche), are either flattened or two-clawed picks, which are worked entirely by the arms, and keep the operator constantly bent almost to the ground; or long-handled wooden spatula also worked solely by the arms, but with the body in a more erect position. Both kinds equally suppose a bare-footed operator, like the Grecian and Peruvian gardeners, and those of France and Italy at the present day.
32. It is said that the browsing of a goat gave the first idea of pruning the vine, as chance, which had set fire to a rose-tree, according to Acosta (Histoire Nat. des Indes), gave the first idea of pruning the rose. Theophrastus informs us that fire was applied to the rose-trees in Greece to enrich them, and that without that precaution they would bear no flowers.

33. The origin of the art of grafting has been very unsatisfactorily accounted for by Pliny and Lucretius. The crossing, rubbing, and subsequent growing together of two branches of a crowded tree or thicket, are more likely to have originated the idea; but when this was first noticed, and how grafting came to be used for the amelioration of fruits, will probably ever remain a secret. Macrobius, a Roman author of the fifth century, according to the taste of his time, says, Saturn taught the art to the inhabitants of Latium. It does not appear to have been known to the Persians, or the Greeks, in the time of Homer, or Hesiod; nor, according to Chardin, is it known to the Persians at this day. Grafting was not known in China till very lately; it was shown to a few gardeners by the Missionaries, as it was to the natives of Peru and South America, by the Spaniards. Some, however, infer from a passage in Manlius, that it may have been mentioned in some of Hesiod’s writings, which are lost.

34. The culture of fruits and culinary plants must have been preceded by a considerable degree of civilisation. Moses gave some useful directions to his people on the culture of the vine and olive. For the first three years, they are not to be allowed to ripen any fruit; the produce of the fourth year is for the Lord or his priests; and it is not till the fifth year that it may be eaten by the planter. This must have contributed materially to their strength and establishment in the soil. The fruit-trees in the gardens of Alcinoüs were planted in quincunx; there were hedges for shelter and security, and the pot-herbs and flowers were planted in beds; the whole so contrived as to be irrigated. Melons in Persia were manured with pigeon’s dung, as they are to this day in that country. After being sown, the melon tribe produce a bulk of food sooner than any other plant; hence the value of this plant in seasons of scarcity, and the high price of doves’ dung during the famine in Samaria (2 Kings, vi. 25.), when a cab, not quite three pints of corn measure, cost five pieces of silver.

Chap. II.

Chronological History of Gardening, from the time of the Roman Kings, in the sixth century B.C., to the Decline and Fall of the Empire in the fifth century of our era.

35. Gardening among the Romans we shall consider, 1. As an art of design or taste: 2. In respect to the culture of flowers and plants of ornament: 3. As to its products for the kitchen and the dessert: 4. As to the propagation of timber-trees and hedges; and 5. As a science, and as to the authors it has produced. In general it will be found that the Romans copied their gardening from the Greeks, as the latter did from the Persians, and that gardening like every other art extended with civilisation from east to west.

Sect. I. Roman Gardening as an Art of Design and Taste.

36. The first mention of a garden in the Roman History is that of Tarquinius Superbus, B.C. 534, by Livy and Dionysius Halicarnassus. From what they state, it can only be gathered that it was adjoining to the royal palace, and abounded with flowers, chiefly roses and poppies. The next in the order of time are those of Lucullus, situated near Baiae, in the bay of Naples. They were of a magnificence and expense rivalling that of the eastern monarchs; and procured to this general, the epithet of the Roman Xerxes. They consisted of vast edifices projecting into the sea; of immense artificial elevations; of plains formed where mountains formerly stood; and of vast pieces of water, which it was the fashion of that time to dignify with the pompous titles of Nilus and Eniris. Lucullus had made several expeditions to the eastern part of Asia, and it is probable, he had there contracted a taste for this sort of magnificence. Varro ridicules these works for their amazing sumptuousness; and Cicero makes his friend Atticus hold cheap those magnificent waters, in comparison with the natural stream of the river Fibrenus, where a small island accidentally divided it. (De Legibus, lib. ii.) Lucullus, however, had the merit of introducing the cherry, the peach, and the apricot from the East, a benefit which still remains to mankind. (Plutarch in vita Lucullii; Sallust; and Varro de Re Rustica.)

37. Of the gardens of the Augustan age of Virgil and Horace, generally thought to be that in which taste and elegance were eminently conspicuous, we know but little. In a garden described by the former poet in his Georgics (lib. iv. 121.), he places only
chicory, cucumbers, ivy, acanthus, myrtle, narcissus, and roses. — Both Virgil and Propertius mention the culture of the pine-tree as beloved by Pan, the tutelar deity of gardens; and that the shade of the plane, from the thickness of its foliage, was particularly agreeable, and well adapted for convivial meetings. The myrtle and the bay they describe as in high esteem for their odor; and to such a degree of nicety had they arrived in this particular, that the composition or mixture of odoriferous trees became a point of study; and those trees were planted adjoining each other, whose odors assimilated together. Open groves in hot countries are particularly desirable for their shade, and they seem to have been the only sort of plantation of forest-trees then in use. From Cicero and the elder Pliny, we learn that the quincunx manner of planting them was very generally adopted; and from Martial, that the manner of clipping trees was first introduced by Cneus Matius, a friend of Augustus. Statues and fountains, according to Propertius, came into vogue about the same time, some of them casting out water in the way of jets d'eau, to occasion surprise, as was afterwards much practised in Italy in the dawn of gardening in the sixteenth century.

38. The gardens and pleasure-grounds of Pliny the consul are described at length in his Letters, and delineations of their ichnography have been published by Felibien in 1699, and by Castell in 1728. Some things, which could only be supplied by the imagination, are to be found in both these authors; but on the whole their plans, especially those of Castell, may be considered as conveying a tolerably correct idea of a first-rate Roman villa, as in the Laurentium, and of an extensive country-residence, as in the Tuscum.

39. The Villa Laurentum was a winter residence on the Tiber, between Rome and the sea; the situation is near Paterno, seventeen miles from Rome, and is now called San Lorenzo. The garden was small, and is but slightly described. It was surrounded by hedges of box, and where that had failed, by rosemary. There were platforms and terraces; and figs, vines, and mulberries were the fruit-trees. Pliny seems to have valued this retreat chiefly from its situation relatively to Rome and the surrounding country, which no walls, fortresses, or belt of wood, hid from his view. On this region he expatiates with delight, pointing out all “the beauty of his woods, his rich meadows covered with cattle, the bay of Ostia, the scattered villas upon its shore, and the blue distance of the mountains; his porticoes and seats for different views, and his favorite little cabinet in which they were all united. So great was Pliny’s attention in this particular, that he not only contrived to see some part of this luxurious landscape from every room in his house, but even while he was bathing, and when he reposed himself! for he tells us of a couch which had one view at the head, another at the feet, and another at the back.” (Preface to Malthus’s Introduction to Girdonin’s Essay, &c. p. 20.)

We may add with Eustace and other modern travellers, that the same general appearance of woods and meadows exists here to this day.

40. Pliny’s Tuscum, or Tusculan Villa (fig. 2.), now Frascati, was situated in a natural amphitheatre of the Apennines, whose lofty summits were then, as now, crowned with forests of oak, and their fertile sides richly covered with corn-fields, vineyards, copses, and villas. Pliny’s description of this retreat, though well known, is of importance, as showing what was esteemed good taste in the gardens and grounds of a highly accomplished Roman nobleman and philosopher, towards the end of the first century, under the reign of Trajan, when Rome was still in all her glory, and the mistress of the world in arts and in arms.

41. A general tour of the Tuscan Gardens is given by Malthus and Dr. Falconer. Their extent, Malthus thinks, may have been from three to four acres, and their situation round the house.

Beginning there, the xystus or terrace (5), says the author of the Historical Essay, is described as in the front of the portico, and near to the house; from this descended a lawn covered with acanthus or moss (15), and adorned with figures of animals cut out in box-trees, answering alternately to one another. This lawn was again surrounded by a walk enclosed with tontii evergreens sheared into a variety of forms. Beyond this was a place of exercise (2), of a circular form, ornamented in the middle with box-trees sheared as before into numberless different figures, together with a plantation of shrubs kept low by clipping. The whole was fenced in by a wall covered by box rising in different ranges to the top.

Proceeding from another quarter of the house, there was a small space of ground, shaded by four plane-trees (7), with a fountain in the centre, which, overflowing a marble basin, watered the trees and the verdure beneath them. Opposite to another part of the building was a plantation of trees, in form of a hippocdrome (6), formed of box and plane trees alternately planted, and connected together by ivy. Beyond this were bay-trees, and the ends of the hippocdrome, which were semicircular, were formed of cypresses (5). The internal walks were bordered with rose-trees, and were in a winding direction, which however terminated in a straight path, which again branched into a variety of others, separated from one another by box-hedges; and these, to the great satisfaction of the owner, were sheared into a variety of shapes and letters (10), some expressing the name of the master, others that of the artificer, while here and there small obelisks were placed, intermixed with fruit-trees.

Further on was another walk, ornamented with trees sheared as above described, at the upper end of which was an alcove of white marble shaded by vines, and supported by marble pillars, from the seat of which recess issued several streams of water, intended to appear as if pressed out by the weight of those which reposed upon it, which water was again received in a basin, that was so contrived as to seem always full without over flowing. Corresponding to this was a fountain, or jet d’eau, that threw out water to a considerable height, and which ran off as fast as it was thrown out. An elegant marble summer-
42. The details of the Tusculan Villa are thus given by Castell. (Fig. 3.)

(1) Villa, or house.
(2) Gestatio, or place of exercise for chariots.
(3) Ambulatio, or walk surrounding the terraces.
(4) The slopes, with the forms of beasts cut in box.
(5) The xystus, or terrace, before the porticus, and on the sides of the house.
(6) The hippodrome, or plain so called, on the north side of the house.
(7) Plane trees on the straight bounds of the hippodrome.
(8) Cypress trees on the semicircular bounds of the hippodrome.
(9) The stibadium and other buildings in the garden.
(10) Box cut into names and other forms.
(11) The pratulum, or little meadow in the garden.
(12) The imitation of the natural face of some country in the garden.
(13) The walk, covered with acanthus or moss.
(14) The meadows before the gestatio.
(15) The tops of the hills, covered with aged trees.
(16) The underwood on the declivities of the hills.
(17) Vineyards below the underwood.
(18) Corn-fields.
(19) The river Tiber.
(20) The temple of Ceres, built by Mustius.
(21) The farmery.
(22) Vivarium, or park.
(23) Vinerium, or orchard.
(24) Orchard.
(25) Apiary.
(26) Cochlearium, or snailery.
(27) Glirarium, or place for dormice.
(28) Osier-ground.
(29) Aqueduct.

Villa of the Ancients, p. 31, and Plate Thirteenth.

43. That the style of Pliny's villas gave the tone to the European taste in gardening up to the end of the 17th century is sufficiently obvious. It is almost superfluous to remark,
observes the author of the Historical View, the striking resemblance which Pliny's gardens bear to the French or Dutch taste. The terraces adjoining to the house; the lawn declining from thence; the little flower-garden, with the fountain in the centre; the walks bordered with box, and the trees sheared into whimsical artificial forms; together with the fountains, alcoves, and summer-houses, form a resemblance too striking to bear dispute." In an age," observes Lord Walpole, "when architecture displayed all its grandeur, all its purity, and all its taste, when arose Vespasian's amphitheatre, the temple of Peace, Trajan's forum, Domitian's bath, and Adrian's villa, the ruins and vestiges of which still excite our astonishment and curiosity; a Roman consul, a polished emperor's friend, and a man of elegant literature and taste, delighted in what the mob now scarcely admire in a college-garden. All the ingredients of Pliny's garden correspond exactly with those laid out by London and Wise on Dutch principles; so that nothing is wanting but a parterre to make a garden in the reign of Trajan serve for the description of one in the reign of King William." — The open country round a villa was managed, as the Roman agricultural writers inform us, in the common field system lately prevalent in Britain; there were few or no hedges, or other fences, or rows of trees, but what was not under forest was in waste, with patches of fallow or corn. Thus it appears that the country residence of an ancient Roman, not only as to his garden, as Lord Walpole has observed, but even as to the views and prospects from his house, as Eustace and Malthus hint, bore a very near resemblance to the chateau of a French or German nobleman in the 18th century, and to not a few in France and Italy at the present day. — The same taste as that displayed by Pliny appears to have prevailed till the fall of the Roman empire; and by existing in a faint degree in the gardens of religious houses during the dark ages, as well as in Pliny's writings, has thus been handed down to modern times.

44. The progress of gardening among the Romans was much less than that of architecture. Professor Hirschfield remarks (Theorie des Jardins, tom. i. p. 25.), that as the descriptions of the ancient Roman authors make us better acquainted with their country-houses than with their gardens, and as the former appear more readily submitted to certain rules than the latter, we are apt to bestow on the gardens the reputation which really belongs to the country-houses, and give the one a value which does not belong to the other. The different manner in which the ancients speak of country-houses and of gardens, may lead us to judge which of the two objects had attained the highest degree of perfection. The descriptions of the first are not only more numerous but more detailed. Gardens are only mentioned in a general manner; and the writer rests satisfied with bestowing approbation on their fertility and charms. Every country-house had its gardens in the days of Pliny; and it is not too much, taking this circumstance in connection with the remarks of Columella, to hazard a conjecture that even the Romans themselves considered their gardens less perfect than their houses. Doubtless the Roman authors, so attentive to elevate the glory of their age in every thing concerning the fine arts, would have enlarged more on this subject, if they had been able to produce any thing of importance. To decide as to the perfection which a nation has attained in one of the arts, by their perfection in another, is too hazardous a judgment; the error has been already committed in regard to the music of the ancients, and must not be repeated in judging of their gardens. The Romans appear in general to have turned their attention to every thing which bore the impression of grandeur and magnificence; hence their passion for building baths, circuses, colonnades, statues, reservoirs, and other objects which strike the eye. Besides, this taste was more easily satisfied, and more promptly, than a taste for plantations, which required time and patience. In all probability the greater number contented themselves with the useful products of the soil, and the natural beauty of the views, bestowing the utmost attention to the selection of an elevated site commanding distant scenery. — Cicero (De Legg. iii. 15.) informs us that it was in their country-villas that the Romans chiefly delighted in displaying their magnificence; and in this respect, the coincidence in habits between ourselves and that great people is a proud circumstance.

45. The Roman taste in gardens has been condemned as unnatural; but such criticism we consider as proceeding from much too limited a view of the subject. Because the Roman gardens were considered as scenes of art, and treated as such, it does not follow that the possessors were without a just feeling for natural scenery. Where all around is nature, artificial scenes even of the most formal description will please, and may be approved of by the justest taste, from their novelty, contrast, and other associations. If all England were a scattered forest like ancient Italy, and cultivation were to take place only in the open glades or plains, where would be the beauty of our parks and picturesque grounds? The relative or temporary beauties of art should therefore not be entirely rejected in our admiration of the more permanent and absolute beauties of nature. That the ancient Romans admired natural scenery with as great enthusiasm as the moderns, is evident from the writings of their eminent poets and philosophers; scarcely one of whom has not in some part of his works left us the most beautiful descriptions
of natural scenery, and the most enthusiastic strains of admiration of all that is grand, pleasing, or romantic in landscape; and some of them, as Cicero and Juvenal, have depreciated the efforts of art in attempting to improve nature. "Whoever," says G. Mason, "would properly estimate the attachment to rural picturesque among the heathen nations of old, should not confine their researches to the domains of men, but extend them to the temples and altars, the caves and fountains dedicated to their deities. These, with their concomitant groves, were generally favorite objects of visual pleasure, as well as of veneration." (Essay on Design, p. 24.)

Sect. II. Roman Gardening considered as to the Culture of Flowers and Plants of Ornament.

46. Flowers were rare in Roman gardens under the kings, and during the first ages of the republic. But as luxury began to be introduced, and finally prevailed to a great degree, the passion for flowers became so great that it was found necessary to suppress it by sumptuary laws. The use of crowns of flowers was forbid to such as had not received the right to use them, either by the eminence of their situation, or by the particular permission of the magistrates. Some acts of rigor towards offenders did not hinder their laws from being first eluded, and at last forgotten, till that which was originally a distinction became at last a general ornament. Men the most elevated in dignity did not hesitate to set up that elegance of dress and of ornament which is repugnant to the idea of a war-like people; and Cicero, in his third harangue against Verres, reproaches this prince with having made the tour of Sicily in a litter, seated on roses, having a crown of flowers on his head, and a garland at his back.

47. The Flora, or flower-feasts, were observed on the last four days of April; they were attended with great indecency, but they show that the common people also carried a taste for flowers to excess. (Pliny, xiii. 29.; Tertullian. Opera.)

48. The luxury of flowers under Augustus was carried to the extreme of folly. Heligabalus caused his beds, his apartments, and the porticoes of his palace to be strewed with flowers. Among these, roses were the sort chiefly employed, the taste for that flower being supposed to be introduced from Egypt, where, as Athenaeus informs us, Cleopatra paid a talent for the roses expended at one supper; the floor of the apartment in which the entertainment was given, being strewed with them to the depth of a cubit. This, however, is nothing to what Suetonius relates of Nero, who spent upwards of four millions of sesterces, or above thirty thousand pounds, at one supper, on these flowers. From Horace it appears that roses were cultivated in beds; and from Martial, who mentions roses out of season as one of the greatest luxuries of his time, it would appear that it was then the caprice, as at present, to procure them prematurely, or by retardation. Columella enumerates the rose, the lily, the hyacinth, and the gilly-flower, as flowers which may embellish the kitchen-garden; and he mentions, in particular, a place set apart for the production of late roses. Pliny says, the method by which roses were produced prematurely was, by watering them with warm water when the bud began to appear. From Seneca and Martial it appears probable they were also forwarded by means of speculatio, like certain culinary productions to be afterwards mentioned.

49. Scientific assemblages of plants, or botanic gardens, appear to have been unknown to the Romans, who had formed no regular system of nomenclature for the vegetable kingdom. Pliny informs us that Anthony Castor, one of the first physicians at Rome, had assembled a number of medical plants in his garden, but they were, in all probability, for the purposes of his profession. Between 200 and 300 plants are mentioned in Pliny's History, as used in agriculture, gardens, medicine, for garlands, or other purposes, and these appear to be all that were known or had names in general use. (Pliny, Nat. Hist. lib. xii.—xxvi. inclusive.)

Sect. III. Roman Gardening in respect to its Products for the Kitchen and the Dessert.

50. The term Hortus in the laws of the Decemviri, which are supposed to be as old as the establishment of the Romans as a people, is used to signify both a garden and a country-house, but afterwards the kitchen-garden was distinguished by the appellation Hortus Pinguis. Pliny informs us, that a husbandman called a kitchen-garden a second dessert, or a flitch of bacon, which was always ready to be cut; or a salted, easy to be cooked and light of digestion, and judged there must be a bad housewife (the garden being her charge) in that house where the garden was in bad order.

51. The principal fruits introduced to Italy by the Romans, according to Hirschfield (Theorie des Jardins, vol. i. p. 27.) and Sickler (Geschichte, 1 Band.), are the fig from Syria, the citron from Media, the peach from Persia, the pomegranate from Africa, the apricot from Epirus, apples, pears, and plums from Armenia, and cherries from Pontus. The rarity and beauty of these trees, he observes (Theorie des Jardins, vol. i. p. 27.), joined to the delicious taste of their fruits, must have enchanted the Romans, especially on their first introduction, and rendered ravishing to the sight,
gardens which became insensibly embelished with the many productions which were poured into them from Greece, Asia, and Africa.

52. The fruits cultivated in the Romans, in the summit of their power, are described by Pliny (lib. x.), and with the exception of the orange and pine-apple, gooseberry, current, and raspberry, include almost all those now in culture in Europe.

Of kernel fruits they had, apples, twenty-two sorts at least: sweet apples (melocynthos) for eating, and others for cooking. They had one sort without kernel, the kind of which is excellent for summer and winter fruit, melting and hard; some were called libraria: we have our pears. Of quinces, they had three sorts, one was called drupesmens, from its yellowish flesh; they boiled them with honey, as we make marmalade. Of cherries, they had several kinds, the pear-shaped, and a small kind, probably the same as we gather wild. Of melissos, two sorts, large and smaller. Of stone fruits, they had peaches, four sorts, including nectarines, apricots, almonds. Of plums, they had a multiplicity of sorts, black, yellow, red; called asinit, from its smoothness; another damaunum, which had much juice. Of grapes, and even wild vines, may come from that which we now call preus. Of cherries, they had eight kinds, a red one, a black one, a kind so tender as scarcely to bear any carriage, a hard-deshed (barourio), like our Bigarreau, a small one with bitterish flavor (birel), like our little wild black, also a dwarf one not exceeding three feet high. Of the olive, several sorts.

Of berries they had grapes. They had a multiplicity of those, both thick-skinned (duraznos) and thin-skinned; one vine growing at Rome produced 12 amorphous of juice, 54 gallons.

53. The grape and the olive were cultivated as agricultural products with the greatest attention, for which ample instructions are to be found in all the Roman writers on Geoponics. Some plantations mentioned by Pliny are supposed still to exist, as of olives at Terrini and of vines at Fiesoli. Both these bear marks of the greatest age.

54. The culinary vegetables cultivated by the Romans were chiefly the following:

Of the brassica tribe, several varieties. Cabbages, Calumella says, were esteemed both by slaves and kings. Of mustard, cabbages, the pot, savoy, and pale, several.

Ofseeded roots, the turnip, carrot, parsnip, beet, sweet, skirret, and parsnip.

Of spiny and tender plants, they appear to have had at least sorrel. Of paraprogenital plants, asparagus.

55. The luxury of forcing vegetal productions it would appear had even been attempted by the Romans. Specularia, or plates of the lapis specularis, we are informed by Seneca and Pliny, could be split into thin plates, in length not exceeding five feet (a remarkable circumstance, since few pieces larger than a fifth of these dimensions are now any where to be met with); and we learn from Calumella (lib. xii. cap. 3.), Martial (lib. viii. 14. & 68.), and Pliny (lib. xix. 23.), that by means of these specularia, Tiberius, who was fond of cucumbers, had them in his garden throughout the year. They were grown in boxes or baskets of dung and earth, placed under these plates, and removed to the open air in fine days, and replaced at night. Sir Joseph Banks (Hort. Tr. i. 148.) conjectures, from the epigrams of Martial referred to, that both grapes and peaches were forced; and Daines Barrington supposes that the Romans may not only have had hot-houses, but hot-walls to forward early productions. Flues, Sir Joseph Banks observes (Hort. Tr. i. 147), the Romans were well acquainted with; they did not use open fires in their apartments, as we do, but in the colder countries at least, they always had flues under the floors of their apartments. Lyons found the flues, and the fire-place from whence they received heat, in the Roman villa he has described in Gloucestershire. Similar flues and fire-places were also found in the extensive villa lately discovered on the Blenheim estate in Oxfordshire. In Italy the Romans used flues chiefly for baths or sudatories, and in some of these we have seen in the disinterred Greek city of Pompeii, the walls round the apartment are fluid, or hollow, for the circulation of hot air and smoke.

56. The luxury of ice in cooling liquors was discovered by the Romans at the time when they began to force fruits. Daines Barrington notices this as a remarkable circumstance, and adds, as a singular coincidence, the coeval invention of these arts in England.

Sect. IV. Room Gardening considered in respect to the Propagation and Planting of Timber-trees and Hedges.

57. The Romans propagated tree by the methods now in common use in our nurseries. Fruit-trees were generally grafted and inoculated; fruits, figs, and olives raised by cuttings, layers, or suckers; and forest-trees generally propagated by seeds and suckers.

58. Though forest-trees were reared with great care round houses in the city (Hor. Ep. i. 10. 22.), yet it does not appear clear that they were planted in masses or strips expressly for useful purposes. They were planted in rows in vineyards on which to train the vine; and the sorts generally preferred were the poplar and the elm. Natural forests and copses, then, as now, supplied timber and fuel. Trees which do not stole (arboreus cursoria), were distinguished from such as being cut over spring up again (succiae repullulant): of the former class was the larch, which was most in use as timber. Pliny mentions a beam 190 feet long and 2 feet thick.
59. Willows were cultivated for binding the vines to the trees that supported them; for hedges; and for making baskets (Virg. G. ii. 4. 36.): moist ground was preferred for growing them, Udum salicium.

60. Hedges were of various sorts, but we are not informed what were the plants grown in those used for defence. They surrounded chiefly vineyards and gardens; for agriculture was then, as now, carried on in the common or open field manner.

Sect. V. Roman Gardening as a Science, and as to the Authors it produced.

61. The gardening of the Romans was entirely empirical, and carried on with all the superstitious observations dictated by a religion founded on polytheism. Almost every operation had its god, who was to be invoked or propitiated on all occasions. "I will write for your instruction," says Varro to Fundasis, "three books on husbandry, first invoking the twelve dii consentes." After enumerating the gods which preside over household matters, and the common field operations, he adds, "adoring Venus as the patroness of the garden, and offering my entreaties to Lympha, because culture is drought and misery without water." The elements of agriculture, he says, are the same as those of the world—water, earth, air, and the sun. Agriculture is a necessary and great art, and it is a science which teaches what is to be planted and done in every ground, and what lands yield the greatest profit. It should aim at utility and pleasure, by producing things profitable and agreeable, &c.

62. Lunar days were observed, and also lucky and unlucky days, as described by Hesiod. Some things, Varro observes, are to be done in the fields while the moon is increasing; others on the contrary when she is decreasing, as the cutting of corn and underwood. At the change of the moon pull your beans before daylight; to prevent rats and mice from preying on a vineyard, prune the vines in the night-time: sow vetches before the twenty-fifth day of the moon, &c. "I observe these things," says Agrarius, (one of fifty authors who Varro says had written on husbandry, but whose writings are now lost,) "not only in shearing my sheep, but in cutting my hair, for I might become bald if I did not do this in the wane of the moon."

63. Religion and magic were also called in to the aid of the cultivator. Columella says that husbandsmen who are more religious than ordinary, when they sow turnips, pray that they may grow both for themselves and for their neighbours. If caterpillars attack them, Democritus affirms that a woman going with her hair loose, and bare-footed, three times round each bed will kill them. Women must be rarely admitted where cucumbers or gourds are planted, for commonly green things languish and are checked in their growth by their handling of them.

64. Of vegetable physiology they seem to have been very ignorant. It was a doctrine held by Virgil, Columella, and Pliny, that any scion may be grafted on any stock; and that the scion partaking of the nature of the stock, had its fruit changed in flavor accordingly. Pliny mentions the effect of grafting the vine on the elm, and of drawing a vine shoot through the trunk of a chestnut; but modern experience proves that no faith is to be given to such doctrines, even though some of these authors affirm to have seen what they describe.

65. Equivocal generation was believed in. Some barren trees and shrubs, as the poplar, willow, osier, and broom, were thought to grow spontaneously; others by fortuitous seeds, as the chestnut and oak; some from the roots of other sorts of trees, as the cherry, elm, bay, &c. Notwithstanding the ignorance and inaccuracy which their statements betray, the Romans were aware of all our common, and some of our uncommon practices: they propagated plants as we do; pruned and thinned, watered, forced, and retarded fruits and blossoms, and even made incisions and ringed trees to induce fruitfulness.

66. There is no Roman author exclusively on gardening, but the subject is treated, more or less, by Cato, Varro, Virgil, Pliny, and Columella.

Cato and Varro lived, the former B. C. 150, and the latter B. C. 28; both wrote treatises on rural affairs, De Re Rustica; but, excepting what relates to the vine and the fig, have little on the subject of gardens. Virgil's Georgics appeared in the century preceding the commencement of our era. Virgil was born in Mantua about B. C. 70; but lived much at Rome and Naples. He appears to have taken most of his ideas from Cato and Varro.

Pliny's Natural History was written in the first century of our era. Pliny was born at or near Rome, and lived much at court. The twelfth to the twenty-sixth book inclusive are chiefly on husbandry, gardens, trees, and medical plants. The Rural Economy of Columella is in twelve books, of which the eleventh, on Gardening, is in verse. He was born at Gadis, now Cadiz, in Spain, but passed most of his time in Italy.
Chap. III.

Chronological History of Gardening, in continental Europe from the Time of the Romans to the present Day, or from A. D. 500 to A. D. 1823.

67. The decline of the Roman Empire commenced with the reign of the emperors. The ages, Hirschfield observes, which followed the fall of the republic, the violence committed by several of the emperors, the invasion of the barbarians, and the ferocity introduced by the troubles of the times, extinguished a taste for a country life, in proportion as they destroyed the means of enjoying it. So many injuries falling on the best provinces of the Roman empire, one after another, soon destroyed the country-houses and gardens. Barbarism triumphed over man and the arts, arms again became the reigning occupation, superstition allied itself to warlike inclinations, and spread over Europe a manner of thinking far removed from the noble simplicity of nature. The mixture of so many different nations in Italy did not a little contribute to corrupt the taste; the possessions of the nobles remaining without defence, were soon pillaged and razed, and the earth was only cultivated from necessity. Soon afterwards the first countries were considered those where one convent raised itself beside another. Architecture was only employed in chapels and churches, or on warlike forts and castles. From the establishment of the ecclesiastical government of the Popes in the eighth to the end of the twelfth century, the monks were almost the only class in Europe who occupied themselves in agriculture; many of these, carried away by their zeal, fled from the corruption of the age, and striving to overcome their passions, or indulge their gloomy humor, or, as Herder observes, to substitute one passion for another, retired into solitary deserts, unhealthy valleys, forests, and mountains; there they labored with their own hands, and rendered fertile, lands till then barren from neglect, or in a state of natural rudeness.

68. Thus the arts of culture were preserved by the monks during the dark ages. The sovereigns, in procuring pardon of their sins by bestowing on the monks extensive tracts of country and slaves, recompensed their activity as rural improvers. The monks of St. Basil and St. Benedict, Harte informs us, rendered many tracts fertile in Italy, Spain, and the south of France, which had lain neglected ever since the first incursions of the Goths and Saracens. Others were equally active in Britain in ameliorating the soil. Walker (Essays) informs us that even in the remote island of Iona, an extensive establishment of monks was formed in the sixth century, and that the remains of a corn-mill and mill-dam built by them still exist; and indeed it is not too much to affirm, that without the architectural and rural labors of this class of men, many provinces of Europe which at present nourish thousands of inhabitants would have remained deserts or marshes, the resorts only of wild beasts, and the seminaries of disease; and architecture and gardening, as arts of design, instead of being very generally diffused, would have been lost to the greater part of Europe.

69. At length the dawn of light appeared with the art of printing, Luther, and Hen. VIII. Commerce began to flourish in Italy and Holland, arts of peace began to prevail, and the European part of what was formerly the Roman empire gradually assumed these political divisions which it for the greater part still retains. We shall take a cursory view of the progress of gardening in each of these states, from the dark ages to the present day.

Sect. I. Of the Revival, Progress, and present State of Gardening in Italy.

70. The blessings of peace and of commerce, the remains of ancient grandeur still existing, and the liberty which some cities had acquired through the generosity and splendor of some popes and princes, united with other causes in the revival of the arts in Italy rather than in any other country.

Subsect. 1. Italian Gardening, in respect to Design and Taste.

71. The earliest notice of Italian gardening is in the work of Pierre de Crescent, a senator of Bologna. He composed in the beginning of the fourteenth century a work on agriculture, which he dedicated to Charles II. king of Naples and Sicily. In the eighth book of this work the author treats of gardens of pleasure. These he divides into three classes; those of persons of small fortune: those of persons in easy circumstances; and those of princes and kings. He teaches the mode of constructing and ornamenting each; and of the royal gardens, observes, that they ought to have a menagerie and an aviary; the latter placed among thickets, arbors, and vines. Each of the three classes ought to be decorated with turf, shrubs, and aromatic flowers.

72. Gardening, with the other arts, was revived and patronised by the Medici family in the beginning of the sixteenth century, and the most celebrated gardens of these times, as Roscoe informs us, were those of Lorenzo de Medici, and of the wealthy Bernard Ru-
cellai. They were in the geometric and architectural taste of those of Pliny, and served as models or precedents for other famous gardens which succeeded them till within the last sixty years, when, as Eustace observes, a mixture of the modern or natural-like manner was generally admitted.

73. The taste for distributing statues and urns in gardens is said to have been revived about the beginning of the sixteenth century by Cardinal D'Este, from the accidental circumstance of his having formed a villa on the site of that of the emperor Adrian, near Rome, where finding a number of antiquities, he distributed them over the newly arranged surface. This mode was soon imitated by Francis I. of France, and afterwards by the other countries of Europe. Gardens of plants in pots and vases, began to be introduced about the same time, and were used to decorate apartments, balconies, and roofs of houses as at present.

74. About the end of the sixteenth century, the celebrated Montaigne travelled in Italy, and has left us some accounts of the principal gardens of that age. He chiefly enlarges on their curious hydraulic devices, for which the garden of the Cardinal de Ferrara at Tivoli was remarkable. (Jour. en Ital. tom. ii.)

75. About the beginning of the seventeenth century, L'Adamo, a poem, was written and published at Milan in 1617, by G. B. Andreini, a Florentine. The prints, Warton observes, (Essay on Poets,) that are to represent paradise are full of cleft hedges, square parterres, straight walks, trees uniformly lopt, regular knots and carpets of flowers, groves nodding at groves, marble fountains, and water-works. This may be considered as a poetical assemblage of the component parts of a fine Italian garden in the seventeenth century.

76. After the middle of the seventeenth century, the celebrated Evelyn, the author of Sylva, visited Italy, and has described a number of its principal gardens.

At Genoa he saw the palace of Hieronymo del Negro, "on the terrace or hilly garden, there is a grove of stately trees, among which are sheep, shepherds, and wild beasts, cut very artificially in a grey stone; fountains, rocks, and fish-ponds. Casting your eyes one way, you would imagine yourself in a wilderness and silent country; sideways, in the heart of a great city."

At and near Florence, he says, there are more than a thousand palaces, and country-houses of note. He particularizes those of Boboli at the ducal residence (now the palace Pitti), in the town, which still exist and are kept in tolerable order.

In and near Rome, he mentions those of the Borghese family, and of Cardinal Aldobrandini at Frascati, "surpassing, in my opinion, the most delicious places I ever beheld for its situation, elegance, plentiful waters, groves, ascents, and prospects." He admires several hydraulic conceits, some of which still exist, and also that "of a copper ball, supported by a jet of air issuing from the floor, and continually dancing about."

At Tivoli he visited the palace and gardens of Este, which are mentioned with similar encomiums. Of the palaces and gardens of Lombardy, he observes, "No disgrace in this country to be some generations in finishing their palaces, that, without exhausting themselves by a vast expence at once, they may at last erect a sumptuous pile." "An Italian nobleman," Forsyth remarks, "will live on a crown a day, but spend millions for the benefit of posterity, and the ornament of his country."

At Vignarini, near Vicenza, he found an orangery, "eleven score paces long, full of fruit and blossoms. In the centre of the garden, a magnificent wire cupola, supported by slender brick piers, and richly covered with ivy. — A most inextricable labyrinth." (Memoirs by Bray, vol. i. 75—207.)

77. In the beginning of the eighteenth century Italy was visited by Volkman, a German traveller, whom Hirschfield considers as deserving credit, and a good judge. He represents the Italian gardens as inferior to those of France in point of superb alleys, lofty cleft hedges, and cabinets of verdure; but, he adds, that they please the greater part of travellers from the north of Europe, more than the French gardens, from the greater variety of plants which they contain, and their almost perpetual luxuriance and verdure. Among the fine gardens, he includes those of Venerie, Stupigni, and Vigne de la Reine, near Turin, which do not appear to have been visited by Evelyn. The beauties of most of the gardens near Rome, he considers as depending more on their situations, distant views, classic remains and associations, luxuriant vegetation, and fine climate, than on their design, which, he says, exhibits "all the puerilities of the French taste, without its formal grandeur." (Nachrichten von Italien, 1 ster band.)

78. About the middle of the eighteenth century the English style of gardening began to attract attention in Italy, though partly from the general stagnation of mind, and partly from the abundance of natural beauty already existing, it has never made much progress in that country. "Unfortunately," observes Eustace (Tour, i. 426.), a traveller abundantly partial to Italy, "the modern Romans, like the continental nations in general, are not partial to country residence. They may enjoy the description or commend the representation of rural scenes and occupations in books and pictures; but they feel not the beauties of nature, and cannot relish the calm, the solitary charms of a country life."

The Italians in general, he elsewhere adds (i. 98.), have very little taste in furnishing a house, or in laying out grounds to advantage. — Notwithstanding these remarks, and the known paucity of specimens of landscape gardening in Italy, an Italian author of eminence, Professor Malacarne of Padua, has lately claimed for Charles Imanuel, first Duke of Savoy, the honor of having invented and first displayed an English garden or park in the neighbourhood of Turin; and which park he proves by a letter of Tasso, that poet wished to immortalise "as much as he could," in the well-known stanza of his Jerusalem, which Chaucer copied, and which Warton and Eustace suggest as more
likely to have given the first idea of an English garden, than Milton’s description of Paradise. (New Mon. Mag. for July 1820; Pindemonte su i Giardini Inglese, Verona, 1817.)

79. Of the present state of gardening in Italy, as an art of design, we shall submit a slight sketch, partly from writers of the present century, and partly from our own inspection in 1819. The grand object of an Italian nobleman is to produce a huge pile of architecture, externally splendid, and to collect a gallery of pictures and statues. The furnishing of this pile for domestic use, or even the internal finishing of great part of it, he cares little about; and the park or gardens are inferior objects of attention. The Romans, when at the highest point of power, seem to have had exactly the same taste, as may be gathered from their writings, and seen in the existing ruins of the Villa Adriana, near Tivoli, and many others.

80. Near Turin, the palace and gardens of Venerie still exist, but are only remarkable for extent, and for an old orangery nearly six hundred feet in length. The surface of the park is irregular, and the trees distributed in avenues, alleys, and geometrical figures; the grounds of some of the numerous white villas near the city are romantic, and command extensive prospects; but very few aspire to the character of fine gardens.

81. At Genoa the best garden is that of Sig. di Negro, situated within the city. It is elevated, irregular, and singularly varied; rich in views of the town, the sea, and the mountains; abounds in fruits, botanical riches, shady and open walks, turrets, and caves. There is one large cave in which dinner-parties are frequently given by the proprietor; and once a year, we believe on his birth-day, this grotto is decorated with some hundreds of religious puppets in gilt dresses, accompanied with pictures of saints, sculls, crucifixes, relics, tapers, and lamps. This forms a part of the gardener’s business, who preserves these paraphernalia through the rest of the year in a sort of museum. We mention the circumstance as characteristic of the Italian taste for spectacle, so different from that of the English. The gardens of Hipolito Durazo, and of Grimaldi, are more extensive, but less select than those of S. di Negro. Like them they are singularly varied in surface, and rich in marine views. The whole coast from Savonna to Genoa, and from Genoa to Nervi, is naturally very irregular, and abounds in beautiful gardens, abundantly stocked with orange trees, partly in pots, and in the warmest situations trained against walls, or planted as standards. We visited many of these gardens, and the only general fault seemed to be the want of order and keeping; properties which are essential to the full effect of every style in every country.

82. The gardens of Lombardy are the most luxuriant in vegetation, not only in Italy, but perhaps in Europe. The climate is not so favorable for the perfection of the grape and the orange as that of Naples, nor for the production of large turnips and succulent cabbages as that of Holland; but it possesses a medium of temperature and humidity between the two climates which is perhaps favorable to a greater number of vegetable productions, than any one climate on the face of our globe. There are few princely gardens in this kingdom, but many of moderate size well stocked with trees and plants of ornament, and sometimes neatly kept.

The gardens of the Brenta still retain marks of their ancient celebrity.

The extent and beauty of those of the Isola Bella (fig. 4), have been greatly exaggerated by Eustace, and other travellers. The justest description appears to us to be that of Wilson. “Nothing,” he says, “can be so noble as the conversion of a barren rock, without an inch of earth on its surface, into a paradise of fertility and luxury. This rock, in 1640, produced nothing but mosses and lichens, when Vitaliano Boromeo conceived the idea of turning it into a garden of fruits and flowers. For this purpose, he brought earth from the banks of the lake, and built ten terraces on arches, one above the other, to the top of the island on which the palace is posted. This labor has produced a most singular pyramid of exotics and other plants, which make a fine show, and constitute the chief ornament of this miracle of artificial beauty. The orange and lemon trees are in great luxuriance, and the grove of laurels (L. nobilis) is hardly to be equalled any where in Europe; two of them in particular are said to be the largest known in existence.” (Wilson’s Tours, vol. iii. p. 449.)

At Monza, the royal residence, near Milan, is the finest garden scenery in Italy. The park contains upwards of 3000 acres, of a gently varied fertile surface. It is chiefly laid out in the regular style; but contains also an English garden of considerable extent and beauty. It is well watered, and the walks are not so numerous as to disturb the unity and repose of the scenes. The culinary, flower, botanic, and
fruit gardens, orangeries, and hot-houses, are all good, and as well managed as the penuriousness of the present vice-king will admit. Very fine avenues lead from this residence to Milan. The whole was begun in Beauchamp's time, under the direction of Sig. Villaresi, one of the most scientific gardeners in Italy, and is his direct inheritor.

There are various gardens pointed out to strangers as English, veramente Inglese, near Milan, and also at Verona, Vicenza, Brescia, Porta, &c; and Buanaparte caused a small public garden to be made in the vigno in the villaggio near the lake of Como.” Wilson observes, “it is most delightful to behold the lofty cypresses, and the highly cultivated gardens, with hot-houses of exotic trees, sweeten the air, and ornamental summer-houses, subduing the natural wildness of the situation.” Most of those which we visited were too much ornamented, and too full of walls, seats, arbors, and other ornaments, for that repose with simplicity which, for the new and the English, is essential to an English garden. Art, in most of these gardens, is as much avowed as in the French style; whereas, in the true English garden, though art is employed, yet it is not avowed and ostentatiously displayed; on the contrary, the grand object is to follow the directions of the Italians themselves, and study that the art “che tutto, nulla si scopre.”

83. At Florence, the ducal gardens of Boboli are the most remarkable. They occupy two sides of a conical hill, and part of a bottom, and consist of three parts; a botanic and exotic garden close to the palace Pitti and the celebrated museum; a kitchen-garden, near the hill top; and, a geometric garden which occupies the greater part of the hill. The scene abounds in almost every ingredient of the style in which it is laid out. The ground being very steep, almost all the walks slope considerably; but a few, conducted horizontally, are level, and serve, if the expression be admissible, as resting walks. There are abundance of seats, arbors, vases, planted with agaves and orange-trees; and a prospect tower on the summit, from which, as well as from many other points, are obtained fine views of Florence and the environs. In the lower part or bottom is a handsome basin of water, with an island and fountains in the centre, verged with a marble parapet ornamented with vases of orange-trees, and surrounded by shrub hedges and statues. On the whole, nothing has spared to render these gardens complete of their kind, and the effect is perhaps as perfect as the situation, from its irregularity and steepness, admits of. The public promenade to the Caffino, deserves notice as among the best in Italy. It consists of shady avenues, extending for several miles on a flat surface near the Arno, varied by occasional views of villas and distant scenery.

The trees are chiefly elms and chestnuts. There are numerous private gardens round Florence, but none of them remarkable. The fortuitous scenery of Vallombrosa and other romantic situations, are the grand attractions for strangers. On mount Fiesole and thence to Bologna, are some country-seats with lodges, and winding approaches, which, considering the arid soil, are highly beautiful, and come the nearest to those of England in any of the warmer regions of Italy. The Tuscan, Sigismondi obser

84. The villas of Rome, Forsyth observes, are to this day the “ocelli Italia.” Their cassinos generally stand to advantage in the park, light, gay, airy, and fanciful. In the ancient villas the buildings were low, lax, diffused, and detached. In the modern, they are more compact, more commodious, and rise into several stories. In both, the gardens betray the same taste for the unnatural, the same symmetry of plan, architectural groves, devices cut in box, and tricks performed by the hydraulic organ. (Rem. on Italy, 173.)

A few cardinals, he elsewhere observes, created all the great villas of Rome. Their riches, their taste, their learning, their leisure, their frugality,—all conspired in this single object. While the eminent founder was squandering thousands on a statue, he would allot but one crown for his own dinner. He had no children, no stud, no dogs to keep; he built indeed for his own pleasure, or for the admiration of others; but he embellished his country, he promoted the resort of rich foreigners, and he afforded them a high intellectual treat for a few pence, which never entered into his pocket. This taste generally descends to his heirs, who mark their little reigns by successive additions to the stock. How seldom are great fortunes spent so elegantly in England! How many are absorbed in the table, the field, or the turf! Expenses which centre and end in the rich egotist himself? What English villa is open like the Borghese, as a common drive to the whole metropolis? (Rem. on Italy, 216.)

The Villa Borghese is the most noted in the neighbourhood of Rome. It has a variety of surface formed by two hills and a dell, and a variety of embellishments, cassinos, temples, groves, fountains, mountains, sculptured fountains, a crowd of statues, a lake, an aqueduct, a circus; but it wants the more beautiful variety of an English garden; for here you must walk in right lines, and turn, at right angles, fatigued with the monotony of eternal ax.

85. In many of the villas on the lake of Como,” Wilson observes, “it is most delightful to behold the lofty cypresses, and the highly cultivated gardens, with hot-houses of exotic trees, sweeten the air, and ornamental summer-houses, subduing the natural wildness of the situation.” Most of those which we visited were too much ornamented, and too full of walls, seats, arbors, and other ornaments, for that repose with simplicity which, for the new and the English, is essential to an English garden. Art, in most of these gardens, is as much avowed as in the French style; whereas, in the true English garden, though art is employed, yet it is not avowed and ostentatiously displayed; on the contrary, the grand object is to follow the directions of the Italians themselves, and study that the art “che tutto, nulla si scopre.”
The Villa Panfilii displays the most architectural gardens of any about Rome. Here, as Forsyth observes, laurel porticoes of ilex, green scutheons, and clipt coronets, are seen vegetating over half an acre; theatres of jets d'eau, geometrical terraces, built rocks, and measured cascades. This might not be antiquated; but as far as respects gardens, the description, if faithful, might be tiresome and monotonous. Even Eustache allows that "howsoever Italian gardens may differ in extent and magnificence, their principal features are nearly the same; the same with regard to artificial as well as natural graces. Some ancient remains are to be found in all, and several in most of them. They are all the same every year from spring to summer and the great sights of the ancient scenery. They are in general much neglected, but for that reason the more rural." (Classical Tour, vol. i. chap. 18.)

85. At Frascati, Belvideere, a villa of Prince Borghese, commands most glorious prospects, and is itself a fine object, from the scenic effect of its front and approaches. Behind the palace is an aquatic stream, which flows from Mount Algidus, dashes precipitately down a succession of terraces, and is tormented below into a variety of tricks. The whole court seems alive at the turning of a cock. Water attacks you on every side; it is dictated in your face from invisible holes; it darts up in a constellation of jets d'eau; it returns in misty showers, which present against the sun a beautiful Iris. Water is made to blow the trumpet of a centaur, and the pipe of a cyclops; water plays two organs; makes the birds warble, and the muses tune their reeds; sets Pegasus neighing, and all Parnassus on music. "I remark," says Forsyth, "this magnificent toy as a specimen of Italian hydraulic arts. Its sole object is to surprise strangers, for all the pleasure that its repetitions can impart to the owners is but a faint reflection from the pleasure of others."

86. At Naples the gardens possess the same general character as those of Rome, though, with the exception of Caserta, they are less magnificent. The royal gardens at Portici are chiefly walled cultivated enclosures, abounding in oranges, figs, and grapes, with straight alleys and wooded quadrants entirely for shade. There is one small department, of a few perches, devoted to the English taste; but it is too small to give any idea of that style. There is also a mountain called Monte Lerno, in which, says Starko (Lettera, ii. 193), the present king has placed swings and wooden horses, or hurly-burly's, (such as are to be seen at our fairs), for his own particular amusement, and that of his nobility. The approach to this garden is through the palace court, great part of which is occupied by a barrack by troops. The fifth and stench of this court is incredible; and yet it is overlooked by the windows of the king's dinner-rooms, who sits dinning in the place, as are passed through the palace on the 2d of August 1819. We know no scene to which it could be compared, but that of the court-of some of the large Russian inns in the suburbs of Petersburgh.

The gardens of Prince Leopold at Villa Francia almost adjoin those of the king. They are less extensive, but kept in much better order by a very intelligent German. The orange-groves and trellises in both gardens are particularly fine; and in that of Prince Leopold, there is a tolerable collection of plants. There is in Naples a royal garden, in the geometrical style, combining botany and some specimens of the English manner, which is now enlarging; and has the advantage of an elevated situation and fine marine views.

The Chiaia is a public garden on the quay, used as a promenade. The outline is a parallelogram, the area arranged in three alleys, with intermediate winding walks, fountains, rock-works, basins, statues, arches, and without turf, and oranges, flowers, &c. in pots. It is surrounded by a parapet surmounted by an iron fence, and contains cassinios for gambling, cafes, baths, taverns, &c. The view to the bay, and the breezes thence arising, are delightful. It is justly reckoned one of the finest walking promenades in Italy.

Extensive gardens of pots and boxes are common on the roofs of the palaces, and other houses in Naples. Viewed from the streets they have a singular effect, and from their beauty and fragrance, from the fresh breezes in these elevated regions, and the comparative absence of the stench with which the lower atmosphere of Naples is almost continually charged, they are very agreeable to the possessors.

87. The royal residence of Caserta is about seventeen miles from Naples. The palace, in which, as Forsyth observes, the late king sought grandeur from every dimension, is situated in an immense plain, and is a quadrangle, the front of which is upwards of seven hundred feet long. It was begun in 1752, rooted in 1757, but is notyet, and probably never will be finished. The park extends from the palace to a range of mountains at two miles distance, some of which it includes. It may be said to consist of four parts; open pasture, almost without trees, near the palace; woody scenery, or thick groves and copses, partly near to, but chiefly at a considerable distance from, the palace; mountainous scenery devoted to game and the chase, at the extreme distance; and an English garden on one side, skirting the mountains. There are besides, St. Lucio a large village, a silk-factory, a farm, &c.; all of which are described by different tourists; minutely by Vasi, in his Guide to Naples and its Environs, — and plans of the whole are given by L. Vanvitelli, in his Disegni del Reale Palazzo di Caserta.

The cascade and canal of Caserta constitute its most remarkable feature, and that which renders this park, in our opinion, the most extraordinary in Europe. The water is begun to be collected above thirty miles' distance among the mountains, and after being conducted to a valley about five miles from Caserta, is carried off by it an aqueduct consisting of three tiers of arches, nearly two hundred feet high, and two thousand feet long. The volume of water is four feet wide by three and a half feet deep, and moves, as near as we could estimate, at the rate of one foot in two seconds. Arrived at the back of the mountain Gaveta, cut through it, and having a little above the stream between the base and the summit, forms a cascade of fifty feet directly in front of the palace. The waters are now in a large basin, from which, under ground, tunnels and pipes proceed on two sides, for the purposes of supplying the lakes or rivers in the English garden, the fish-ponds, various gardens, and for irrigation to maintain the turf. From the centre of this basin proceed a series of alternate canals and cascades of uniform breadth, and in a direct line down the slope of the hill, and along the plain to within a furlong or little more of the palace. Here it terminates abruptly, the waters being conveyed away under ground for other purposes. The effect of this series of canals and cascades, viewed from the garden-front of the palace, or from the middle entrance-arch, through that "long obscure portico or arcade which pierces the whole depth of the quadrangle, and acts like the tube of a telescope to the waters," is that of one continued sheet
of smooth or stagnant water resting on a slope; or of a fountain which had suddenly burst forth and threatened to inundate the plain; but for this idea the course of the water is too tame, tranquil, and regular, and it looks more like some artificial imitation of water than water itself. In short the effect is still more unnatural than it is extraordinary; for though jets and fountains are also unnatural, yet they present nothing repugnant to our ideas of the nature of things; but a body of water seemingly resting on a slope, and accommodating itself to the inclination of the surface, is a sight at variance with the laws of gravity. Unquestionably the cascade at the extremity is a grand object of itself; but the other cascades are so trifling, and so numerous, as in perspective, and viewed at a distance, to produce this strange effect of continuity of surface. As a proof that our opinion is correct we refer to the views of Caserta, which are got up by the Neapolitan artists for sale; had these artists been able to avoid the appearance in question, even by some departures from truth, there can be no doubt they would not have hesitated to do so. A bird's-eye view of this canal, in Vanvitelli's work (fig. 5), gives but a very imperfect idea of the reality, as seen from the surface of the ground, and especially from the palace and lower parts of the park.

Forsyth seems to have paid little attention to this water, having been chiefly struck with the palace. Eustace says, "The palace is one of the noblest edifices of the kind in Europe; the gardens extensive, regular, but except a part in the English style, uninteresting. From a reservoir on the mountain Gazzano, the water is precipitated down the declivity to the plain, where, collected in a long straight canal, it loses its rapidity and beauty, and assumes the appearance of an old fashioned stagnant pool." (Tour in Italy, vol. i. p. 602.) Wilson says, the cascade of Caserta might have been made the finest of its kind in the world; but it has been spoiled by a love of formality, which has led the capricious stream drizzling over regular gradations of steps into a long stagnant canal. (Barts, &c. vol. ii. p. 217.)

The English garden of Caserta was formed by Graeffe, a German, author of a Catalogue of Herba-
ceous Plants, who had some time in England. He was sent to the king of Naples about 1769, by Sir Joseph Banks, and has formed and preserved as perfect a specimen of English pleasure-ground as any we have seen on the continent. The verdure of the turf is maintained in summer by a partially concealed system of irrigation; and part of the walks were originally laid with Kensington gravel. Every exotic, which at that time could be furnished by the Hammersmith nursery, was planted, and many of them form now very fine specimens. Among these the Camellias, Banksias, Proteas, Magnolias, Pines, &c. have attained a large size, and ripen their seeds. There is a good kitchen and botanical garden, and extensive hot-houses, chiefly in the English form; but now much out of repair. Indeed this remark will apply to the whole place, excepting the palace. Graeffe laid out the gardens of the Duke de San Gallo, at Naples, and various others. He was not liked by the peasants of St. Lucio, who, taking the advantage of him, when thrown from a cabriole, stabbed him mortally before he could recover himself, in 1816.

88. In Sicily are some gardens of great extent. A few are mentioned by Swinburne; and an account of one belonging to a Sicilian prince, remarkable for its collection of monsters, is given in Brydone's Tour.

SUBSECT. 2. Italian Gardening in respect to the Culture of Flowers and Plants of Ornament.

89. Flowers appear to have been little cultivated by the Italians previously to the 10th century. The introduction of the Christian religion as a national worship, though at present favorable, was at first adverse to the use of flowers. Tertullian and Clement of Alexandria, in the second century, inveighed against their use with all their eloquence: and the rites of religion, then carried on in gloomy vaults, were not, as now, accompanied by bands of music, statues, pictures, and enriched altars decorated with flowers. P. de Crescent in the beginning of the fourteenth century, mentions only the violet, lily, rose, gilly-flower, and iris. Commerce began to flourish in the century which succeeded, and various plants were introduced from the Eastern countries, by the wealthy of Venice and Genoa.
90. The earliest private botanic garden was formed at Padua, by Gaspar de Gabriel, a wealthy Tuscan noble, at considerable expense. It was accomplished in 1525; and though not a public institution, it was open to all the curious. To this garden succeeded, that of Corner at Venice, and Simonetta, at Milan; those of some convents at Rome, and of Pinella, at Naples, with others enumerated by botanical historians. (C. Spreng. Hist. lib. iii.; Haller's Lib. Bot. 21.; Tiraboschi's Stor. del Litt. Ital.; Gessner, Hort. German.; Stephanus de Re Hortense.)

91. The first public botanic garden established in Europe was that of Pisa, begun, according to Deleuze, in 1543, by Cosmo de Medici; and of which Ghini, and Celsalpin, celebrated botanists, were successively the directors. Belon, a French naturalist, who was at Pisa in 1555, was astonished at the beauty of the garden, the quantity of plants it contained, and the care taken to make them prosper. In 1591 the number of new plants was found so far accumulated as to render a larger garden necessary, and that space of ground was fixed on which is the present botanic garden; two borders were destined for ornamental flowers, and a green-house was formed for such as were too tender for the open air. In the beginning of the eighteenth century, a great accession was obtained to the garden by the double flowers of Holland, then introduced in Italy for the first time. (Culze, Hist. Pisani.) The example of Pisa was soon imitated by other cities and universities in Italy and Germany. In 1545, (not 1533, as stated by Adamson—see Deleuze,) the public botanic garden of Padua was agreed on by the senate of Venice. It contained in 1581 four hundred plants cultivated in the open air, besides a number kept in pots to be taken into houses or sheds during winter. The garden of Bologna was next established by Pope Pius the Vth; then that of Florence by the Grand Duke; and afterwards that of Rome. From that time to the present day, the numbers of botanic gardens have been continually increasing, so that there is now one belonging to almost every principal city in Italy; an exertion the more remarkable, as botanic gardens in that country are proportionally more expensive than in England, from the necessity of conveying a stream of water to them, and forming a regular system of irrigation.

92. A taste for flowers and ornamental plants has thus become general in Italy; and at the same time the means of gratification afforded, by the superabundant plants and seeds of these gardens being given away, or sold at very moderate prices to the curious. About this time also the Dutch made regular exchanges of their bulbous roots for the orange-trees of Genoa and Leghorn; and the double night-smelling jessamine was introduced at Pisa from Spain, and so highly prized as to have a centinel placed over it by the governor. (Evelyn.) The use of flowers, it is probable, was never entirely laid aside in Italy as ornaments to female dress; but in the progress of refinement their application in this way became more general, and more select sorts were chosen; they became in demand, both gathered in bouquets, and with the entire plants in pots; they were used as household ornaments both internal and external; and the church, thinking that what pleased man must be pleasing to the gods; or conforming to the taste of the times, and desirous of rendering religion as attractive as possible to the multitude, introduced flowers as decorations of altars and statues, and more especially in their fêtes and processions. Pots and boxes of orange trees, pomegranates, bays, oleanders, myrtles, and other plants, are now let out by the day, for decorating the steps and approaches to altars, or sold for ornamenting roofs, balconies, virandas, courts, yards, passages, halls, staircases, and even shops and warehouses in most of the large towns of Italy. Notwithstanding this there is a recent instance on record of a lady residing in Rome, commencing a law-suit against her neighbour, for filling her court-yard with orange-trees, the smell of the flowers of which was by the other considered as a nuisance.

For the church the white lily (Lilium candidum) is in great demand, with which the Madonna, or Madre di Dio, is decorated as an emblem of her virginity. The tubia (T. intifolia) is much used when in season, being considered as the real Christ, to which the soldiers handed him a sponge of vinegar. In Poland, where the tubia has not been easily procured, we have seen leeks in the flower-stalk used as a substitute. The rose, the stock-gilly-flower, the jessamine, &c. are next in demand, and are used in common with such others as are presented gratis, or offered for sale, as decorations, indiscriminately to the crowd of statues and pictures of saints which decorate the churches, to private houses, and as ornaments of female dress.

On occasions of public rejoicing flowers are also much used in Italy. Favorite princes and generals are received into towns and even villages through triumphal arches decorated with flowers, and the ground is also sometimes strewn with them. The lives of Buonaparte, Murat, and Beauharnois, afford many examples. The Emperor of Austria made a tour of Italy in 1819, and though everywhere disliked, wherever walking on a mine ready to explode, he was in many places so received; and at the famous cascade of Marmora, near Termi, a slight arcade, 200 yards in length, was formed to guide the steps of the imperial visitor to the best point of view. It was covered with intersecting wreaths of flowers and foliage, and the sides ornamented with festoons of box, myrtle, and bay. At Milan, a very gay city, flowers are greatly prized, and in the winter season are procured from the peculiarly warm and ever verdant gardens between Genoa and Nice. A Louis-d'or, we were informed, is sometimes paid for a single nosegay. During the carnival the demand is great throughout Italy.

93. Florists' flowers, especially the bulbous kinds, do not succeed well in the dry warm climate of Italy. Fine varieties of the iaycithum, tulip, ranunculus, auricula, polyanthus, &c. are soon lost there, and obliged to be renewed from more temperate countries. They excel, however, in the culture of the tuberose, which forms an article of commerce
at Genoa, as does the paper narcissus (N. orientalis) at Naples. In roses, jessamine, oleanders, oranges, they also excel; and also in most single flowers not natives of cold climates. Sig. Villaresi, already mentioned, has raised from seeds of the Bengal rose (Rosa indica), impregnated promiscuously with other roses, upwards of fifty distinct varieties, many of which are of great beauty, and very fragrant. In general, flowers and ornamental plants are most in demand, and cultivated to the greatest degree of perfection in Lombardy, of which the flower-markets of Milan and Venice afford most gratifying proofs. Many of the Chinese, New Holland, and some of the Cape trees and shrubs, thrive well, and blossom luxuriantly in the open air in the warmer regions, as in S. di Negro’s garden, at Genoa, and those of Pisa and Caserta. Evelyn says, he saw at Florence, in 1664, a rose grafted on an orange-tree; the same tricks are still passed off with the rose, jessamine, oleander, myrtle, &c. at Genoa, and even in some parts of Lombardy.

94. The taste for flowers and plants of ornament is rather on the decline than otherwise in Italy. Much depends on the taste of the princes in this as in every other matter, and unfortunately those of Italy are at present mere ciphers. The king of Naples knows no pleasures but those of the table, the seraglio, and the chase. For the latter enjoyment, the Pope has kindly given him a dispensation to hunt on Sundays. The Pope is debarréd from pleasure by his office; the grand Duke of Tuscany has some taste for plants, but more for a heavy purse; his relation, the vice-king of Lombardy, is more a priest than a prince; though he has some fondness for succulent exotics, of the common sorts of which, he has a large collection. The king of Sardinia is an old man, and a mere king Dei gratia.

Subsect. 3. Italian Gardening in respect to its Products for the Kitchen and the Dessert.

95. The Italian fruits are nearly those of the Romans, to which they have made but few additions, if we except the orange and the pine-apple. The orange is supposed to have been introduced between the time of Pliny and Palladius; it is the fruit in which they excel, more from climate and soil than science. There are supposed to be nearly a hundred varieties of this fruit in Italy; but in the orange-nurseries at Nervi, it is not easy to make out more than forty or fifty distinct sorts. These have mostly been obtained from seeds. They have not the Mandarine orange, nor some varieties of shaddock (C. decumana), which we possess. The most regular and systematic orange-orchards are at Nervi; and the largest trees around Naples, at Sorenta, Amalfi, &c. The more rare sorts are kept in conservatories at Rome, and the largest house, and best collection, is that of the Borghese. At Florence and Milan, all the sorts required to be housed during winter, but at Hieres and Nice in France, and at Genoa and Nervi, they stand the common winters in the open air.

96. The stone fruits in which they excel are the peach and cherry. There are above twenty varieties of peaches cultivated in the neighbourhood of Rome and Naples; and these fruits, grown on standard trees, as apples and pears are in this country, arrive at a very high degree of perfection. They have few sorts of apricots and nectarines, and not many plums; but their Regina Claudia, or gages, are excellent. Cherries and gooseberries are grown in Italy, especially in Tuscany. The Milan or Morello cherry, is noted for its prolific qualities, and for having a consistency and flavor somewhat resembling the Morello esculenta, or morel.

97. The chief berry of Italy is the grape; their varieties are not so numerous as in France or Spain; and are, for the most part, the result of long growth on one soil and situation. Vineyard grapes are indifferent to eat in most parts of Lombardy, and in the best districts are equalled if not excelled by muscats, sweet-waters, muscadines, and other sorts grown in hot-houses in this country. The grape is the only berry that thrives in Italy. It is not kept lower in France; but elevated on trellises near houses and in gardens (fig. 6.), and trained to long poles or trees in the fields. Collections of gooseberries from Lancashire have been introduced at Leghorn, Genoa, and Monza; and, grown in the shade, they thrive moderately at the gardens of the latter place. The currant, the raspberry, and the strawberry, though natives of the Alps and Apennines, do not thrive in the gardens, but are brought to market from the woods; and so is the black mulberry, which is there cultivated for the leaves, as harder than the white, and which Sigismondi at one time considered as a fruit elsewhere unknown.

98. Kernel-fruits in general, especially pears, are excellent in the north of Italy; but indifferent in the warmer regions. Services in considerable variety abound in Piedmont, and part of Lombardy. The pine-apple is cultivated in a few places in Italy, but with little success, excepting at Florence and Milan. There are a few in the royal gardens at Portici, but weak, yellow-leaved, and covered with insects. The few grown in the Pope’s garden, and in one or two other villas near Rome, are little better. By far the best and greatest quantity are in the vice-royal gardens of Monza. The last king of Sardinia sent his gardener, Brochieri, to England...
to study their culture. He returned, and in 1777 published a tract on them; with a plan of soil for their reception; and in this way they are universally grown in Italy. Such, however, is the cultivation, that every climate, the citrouille, or water-melon. Too little care is bestowed in selecting good fruits for seeds, and in preventing hybridism from the promiscuous intercourse with surrounding sorts of cucumis; and, hence, seeds sent from Italy to this country are liable to be depended on, and generally produce varieties inferior to those of British growth. There are a few sorts of cucumbers, and though there are a great number of gourds and pomponis cultivated, the sorts, or conspicuous varieties of both, are less numerous than in this country. Italian cucumbers are never so succulent as those grown in our humble frames.

The love-apple, egg-plant, and capsicum, are extensively cultivated near Rome and Naples for the kitchen; the fruit of the first attaining a larger size, and exhibiting the most grotesque forms. It is singular, that in Sicily this fruit, when ripe, becomes sour, and so unfit for use, that the inhabitants are supplied with it from Naples.

101. Want of demand for the fruits of the northern climates precludes their production. Were it otherwise, there can be no doubt means would soon be resorted to, to produce them in so great perfection as we do their fruits here; all that is necessary is to imitate our climate by abstracting or excluding heat, and supplying moisture; but luxury in Italy has not yet arrived to the degree adequate to produce this effect.

102. Of culinary vegetables, the Italians began with those left them by the Romans, and they added the potatoe to their number as soon as, or before, we did. They now possess all the sorts known in this country, and use some plants as salads, as the chicory, ox-eye daisy, rucola, or rocket (Brassica eruca, L.), which are little used here. The turnip and carrot tribe, and the cabbage, savoy, and radish, thrive best in the northern parts; but the potato grows well every where, and the Italian autumn is favorable to the growth of the cauliflowers, and broccoli, which are found of large size at Rome, Florence, and Bologna, in the months of September and October; and very large at Milan, all the summer and autumn. The legeruminous tribe thrive everywhere; but in some places the entire pod of the kidney-bean is so dry and hard, as to prevent its use as a substanece. In short, the advantages the Italians have the advantage over the rest of Europe in fruits, that good climate is greatly counterbalanced by the inferiority of their culinary vegetables. Much to remedy the defect might be done by judicious irrigation, which in the south of Italy, and even in Lombardy, is so far necessary as to enter into the arrangement of every kitchen-garden. Shading, barren land, and change of seed will effect much; but the value of good culinary vegetables is not known to the greater part of the wealthy Italians.

103. Horticulture has made little progress in Italy. It is not in Italy, Simond observes, that horticulture is to be studied; though nowhere is more produced from the soil by culture, manure, and water; but forcing or prolonging crops is unknown; every thing is sown at a certain season, and grows up, ripens, and perishes together. The variety is not great; they have only three or four sorts of cabbage, not more of kidney-beans, and one of pea; the red and white beet, salsify, scorzonera, chervile, sorrel, onion, schallot, Jerusalem artichoke, are in many places unknown: but they have the cocoma, or water-melon, everywhere. In Tuscany and Lombardy, it is raised on dung, and then transplanted in the fields, and its sugary icy pulp forms the delight of the Italians during the whole month of August. Though they have walls round some gardens, they are ignorant of the mode of training trees on them. (Agr. Tosc.)

Subsec. 4. Italian Gardening, in respect to the planting of Timber-trees and Hedges.

104. The self-sown forests of the Alps and Apennines are the chief resources of the Italians for timber; and timber-trees are chiefly propagated for parks, public walks, and lining the great roads. The vine is still, in many places, trained on the poplar and elm (fig. 7); but in Tuscany and Lombardy, where the culture is deemed superior, the common maple (A. campestre) and flowering ash (Ormus europaeus) are preferred. (Sigamondi, Agr. Toscan.; Chateauvieux, Lettres, &c. 1812.) The most common tree for every other purpose is the narrow-leaved elm, which lines the road from Rome to Naples, for upwards of twenty miles together. Near Milan, the Lombardy poplar is a great deal used; but a late author, Gautieri (Dello Influsso del Boschi, &c. 1817.) argues in favor of cutting down, rather than planting in the Milanese plains. The finest avenues and public equestrian promenades in Italy are those around Milan and at Monza; the trees are of various sorts, as the tulip-tree, platanus, lime, acacia, melia zederach, various oaks, chestnuts, beeches, &c.; they were planted in Beauharnois' time; and such is the rapidity of vegetation in this climate, that already the tulip-trees produce blossoms, and in seven years more the effect will be complete. The sorts are every where mixed, in order that the failure or defective growth of one species may have a chance of being compensated by the growth of that, or of those adjoining; or that if a malady were to attack one sort of tree, it might not lead to continuous defalcation. Most of those trees were planted by Villaresi, who, before the late political changes, had constantly under his direction not fewer than three thousand men for public and royal improvements.

105. The timber-trees of the native forests of Italy are chiefly oak, chestnut, and beech; the undergrowth are of numerous species, including the arbutus, ilex, and myrtle. This class of forests skirts the Alpine mountains, and covers, in many places, the Apennine hills. In higher regions the larch abounds, and in sheltered dells the silver fir. The
stone and cluster pine are confined to the lower regions, as the hills of Tuscany, the vales of Arno, Tiber, &c.

106. Hedges are in general use in Italy, but are very imperfectly formed and managed. In Lombardy the hawthorn is a good deal used; but in Tuscany, the States of the Church, and those parts of the Neapolitan territory which are hedged, the *rhamnus paliurus* is the prevailing plant, mixed, however, with the pyracantha, pomegranate, myrtle, asparagus retrofractus, and with wild roses, brambles, hazels, reeds, &c. seldom without gaps and holes, open or filled up with dead bushes or reeds. The willow alone often forms a hedge in Lombardy, where the shoots are valuable for tying up the vine.

**Subsect. 5. Italian Gardening, as empirically practised.**

107. Gardens in Italy are common to the rural class of citizens. It is a general remark of travellers, and of acknowledged truth, that the state of cottage gardens indicates the state of the cottagers; and those of Italy confirm the justness of the observation. Almost the only plants grown in them are gourds and Indian corn. In Tuscany and Lombardy some of the cabbage tribe, the kidney-bean, and occasionally the potato are to be seen, but rarely any thing else. The gardens of the farmers are somewhat better, especially in the northern districts, where they often contain patches of hemp, potatoes, parsnips, lettuce, and some flowers and fruit-trees. The gardens of small proprietors are still better stocked; those of wealthy bankers and merchants are generally the best in Italy. The gardens of the convicts are, in general, well cultivated, and rich in fruits and culinary vegetables, with some flowers and evergreens for church decorations. The priests assist in their cultivation, and some of these men are much attached to gardening.

108. For commercial purposes gardening is chiefly practised by market-gardeners, who also grow flowers, act as orchardists, and often make wine. There are hardly any nurseries for trees and shrubs in Italy, if we except those for orange-trees at Nervi, and two small ones for general purposes at Milan. Those who form new gardens are chiefly supplied from France, or from their friends, or from private gardens; most of which last sell whatever they have got to spare.

109. The operative part of gardening in Italy is performed more by labourers than by regular apprentices and journeymen; and thus good practical gardeners are more the result of accident than of design. The great defect of both is the want of a taste for order and neatness. The Italians are particularly unskilful in the management of plants in pots, and especially exotics, which require protection by glass. These are put into houses with upright or slightly declining glass fronts, and opaque roofs; there they remain during a winter of from three to five months; want of light and air renders their leaves yellow and cadaverous; and when they are taken out they are placed in the most exposed parts of the garden, often on parapets, benches, or stages. Here the sudden excess of light soon causes them to lose their leaves, which they have hardly time to regain before the period arrives for replacing them in the conservatory or hot-house. We know of few exceptions to this censure, excepting at Monza, and Caserta, where they are kept in winter, in glass-roofed houses, as in England, and placed out in summer under the shade of poplars or high walls. Dr. Oct. Tazetti, professor of rural economy at Florence, who lectures in a garden in which specimens are displayed of the leading sorts of Italian field and garden-culture, acknowledged the justness of this remark.

110. The artists or professors are of two classes. First, The architects, who adopt the rural branch of their art, (*architetti rustici,* ) and who give plans for parks, chiefly or almost entirely in the geometric style, to be executed under their direction, and that of the head gardener. Secondly, The artist-gardeners, (*artisti giardiniere,* ) who are generally the gardeners, or directors of gardens, of some great establishment, public or private, and who give plans for gardens, chiefly in what is there considered the English manner, and for kitchen-gardens; and as in England, either direct, by occasional visits, or undertake by contract, their execution and future occasional inspection.

**Subsect. 6. Italian Gardening, as a Science, and as to the Authors it has produced.**

111. By the establishment of professorships of botany and botanic gardens, in the sixteenth century, the Italians have materially contributed to the study of the vegetable kingdom, without some knowledge of the physiology of which, the practice of gardening must be entirely empirical. Malpighi is considered the father of vegetable physiology in Italy. It must be confessed, however, that the scientific knowledge of the Italians is chiefly confined to their professors and learned men: the practical gardener is yet too ignorant either to study or understand the subject; too much prejudiced to old opinions to receive new ideas; and, partly from climate, but chiefly from political and religious slavery, too indifferent to wish to be informed. Some exceptions must be made in favor of such gardeners as have been apprenticed in botanic and eminent gardens, or under intelligent Germans, who are here and there to be found superintending the gardens of the nobles.
The bastardising of the eucumis tribe, by proximity, and the striking phenomena of the male and female hemp, have introduced some vague ideas of the sexuality of vegetables; but the use of leaves, by far the most important knowledge which a gardener can possess, seems no where understood by ordinary master-gardeners. Grafting and layering are practiced without any knowledge of the effects of the returning sap, or of the exclusion of air and light. Nothing can be worse than the practice of budding orange-trees at Nervi; to be convinced of which, it is only necessary to compare the plants imported from thence, with those brought from Malta or Paris. The culture of the vine, the olive, and the fig, belongs to the rural economy of the country; that of the vine is abundantly careless, and the practice of the caprification of the fig, though laughed at by the professors, is still followed in various places near Rome and Naples.

112. Religious and lunar observances are still followed by the gardeners in most parts of Italy. With the Romans it was customary before any grand operation of agriculture was undertaken, to consult or invoke the god of that department, as of Flora, Pomona, &c. and to pay attention to the age of the moon and other signs. A good deal of this description of ceremony is still carried on in general economy, by the priests and farmers, and gardening has not yet entirely thrown off the same badge of ignorance and religious slavery. Many gardeners regulate their sowings of kitchen-crops by the moon, others call to the priests to invoke a blessing on large breadths of any main crop; some, on minor occasions, officiate for themselves, and we have seen a poor market-gardener at Savonna muttering a sort of grace to the virgin over a bed of new-sown onions. Father Clarici, a priest who published *Istoria e Culture delle Piante*, &c. so late as 1726, countenances most of these practices, and describes many absurd and foolish ceremonies used for procuring good crops, and destroying insects.

113. Of the Italian authors on gardening, few or none are original. Filippo Re has written a great many books, and may be compared to our Bradley. Silvo Sigismondi, of Milan, has written a work on English gardening, resembling that of Hirschfield, of which it is, in great part, a translation. Clarici is a very copious writer on culinary gardening, and the culture of flowers; and the most approved writer on the orange tribe is Gallesio of Savonna.

Sect. II. Of the Revival, Progress, and present State of Gardening in Holland and Flanders.

114. Gardening was first brought to a high degree of perfection in Holland and the Netherlands. The crusades, in the twelfth century, are generally supposed to have excited a taste for building and gardening in the north of Europe. But from Stephanus and Gesner, it appears that a taste for plants existed among the Dutch, even previously to this period. It is to be regretted that scarcely any materials are to be found from which to compose such a history as this interesting circumstance requires. Harte (*Essays on Agriculture*) conjectures that the necessities arising from the original barrenness of the soil (that of Flanders having been formerly like what Arthur Young describes Norfolk to have been nearly a century ago), together with a certain degree of liberty, the result of the remoteness of the situation from kings and priests, may have contributed to improve their agriculture; and that the wealth acquired by the commercial men of Holland, then the most eminent in the world, enabled them to indulge in country-houses and gardens, and to import foreign plants. To this we may add, that the climate and soil are singularly favorable for horticulture and floriculture, the two departments in which the Dutch are most eminent.

Subsect. 1. Dutch Gardening, as an Art of Design and Taste.

115. The Dutch are generally considered as having a particular taste in gardening, yet their gardens, Hirschfield observes, appear to differ little in design from those of the French. The characteristics of both are symmetry and abundance of ornaments. The only difference to be remarked is, that the gardens of Holland are more confined, more covered with frivolous ornaments, and intersected with still, and often muddy pieces of water. The gardens of Ryswick, Houslaerdyk, and Sorgvliet were, in the beginning of the last century, the most remarkable for geometrical beauty of form, richness in trees and plants, and careful preservation. It is singular, our author observes, that the Dutch are so fond of intersecting their gardens with canals and ditches of stagnant water, which, so far from being agreeable, are muddy and ugly, and fill the air with unwholesome vapours. Yet they carry this taste, which has no doubt originated in the nature of their country, to the East Indies; and the numerous country-houses belonging to the Dutch settlement in Batavia are all furnished with gardens and canals like those in the neighbourhood of Amsterdam; as if to render the unwholesome air of that country still more dangerous. Every field is there crossed by a canal; and houses on eminences are surrounded at great expense by moats and draw-bridges like those of the Hague. Such is the influence of habit, and the love of country; and, therefore, how...
ever at variance with local circumstances, and sometimes even with utility, it cannot be altogether condemned.

116. Grassv slopes and green terraces and walks are more common in Holland than in any other country of the continent, because the climate and soil are favorable for turf; and these verdant slopes and mounds may be said to form, with their oblong canals, the characteristics of the Dutch style of laying out grounds.

117. Hague, the Versailles and Kensington of Holland, and in fact the most magnificent village in Europe, contains two royal palaces with their gardens in the ancient style. Evelyn, in 1641, describes them as “full of ornament, close walks, statues, marbles, grozzos, fountains, and artificial music;” and of the views of the village he says, “beautiful lime-trees are set in rows before every man’s house.” Sir J. E. Smith (Tour on the Continent, vol. I) described them in 1783, the one garden as full of serpentine and the other as full of straight lines. In 1814, these gardens had lost much of their former beauty, partly from age and decay, but principally from neglect. Jacob (Travels in Germany), in the same year, found them formal and crowded with high trees. Neil, in 1817, found in them nothing becoming royalty.

118. At Broeck and Alkmaar the ancient style is still maintained in its purity in the villas gardens. M. Seterveldt’s garden near Utrecht is also most carefully preserved specimen. Here the grand divisions of the garden are made by tall thick hedges of beech, hornbeam, and oak, and the lesser by yew and box. There are avenue walks, and berceau walks, the opening of the bow of flowers in the sides, verdant houses, rustic seats, rustic seats (fig. 8.), canals, ponds, grozzos, fountains, statues, and other devices; “and,” adds the horticultural tourist, “we were struck with this circumstance, that every thing in this garden has its most exact counterpart: if there be a pond, or walk, or statues, or a group of evergreens, on one side; the same may, with confidence, be predicted on the other side of the garden; so that the often quoted couplet of Pope, ‘Groove nods at grove, &c.,’ can no where be better exemplified.” (Hort. Tour, 246.)

119. At Brussels, among other curiosities, Evelyn mentions a hedge of jets d’eau, lozenge-fasion, surrounding a parterre; and “the park within the walls of the city formed with whatever may render it agreeable, melancholy, and country-like.” It contained “a stately heronry, divers springs of water, artificial cascades, walks, grozzos, statues, and root-houses.” This park was considerably enlarged some years ago; the then decayed rustic seats, fountains, and more curious water-works removed, and the whole divided by broad sand paths, and decorated with good statues, seats, fountains, and cafes for refreshment.

120. The modern, or English style of gardening, Sir J. E. Smith informs us, was “quite the fashion” in Holland, in 1783; but neither the surface of the ground, the confined limits of territorial property, nor the general attention to frugality and economy, are favorable to this style. Some attempts, on a small scale, may be seen from the canals, but we know of no extensive parks and pleasure-grounds in this manner.

121. An example of a Flemish garden in the English style (fig. 9.) is given by Kraft; it is of small size, but varied by the disposition of the trees, rustic seats, and raised surfaces; and surrounded, as Dutch and Flemish gardens usually are, by a canal. It was laid out by Charpentier, gardener to the senate of France, in the time of Napoleon.

122. The villa of M. Bertrand of Bruges is thus noticed in the Caledonian Horticultural Tour:

"It has extensive grounds, and is flat, but well varied by art. Where the straight walks cross each other at right angles, the centre of the point of intersection is shaped into an oblong parterre, resembling a basket of flowers, and containing showy geraniums in pots, and gaudy flowers of a more hardy kind planted in the earth.

Some things are in very bad taste. At every resting-place, some kind of conceit is provided for surprising the visitant: if he sit down, it is ten to one but the seat is so contrived as to sink under him; if he approaches, or approach the summer-house, water is squirted from concealed or disguised fountains, and he does not find it easy to escape a wetting. The dial is provided with several gnomons, calculated to show the corresponding hour at the chief capital cities of Europe; and also with a lens so placed, that, bringing sunshine, the priming of a small cannon falls under its focus just as the sun reaches the meridian, when of course the cannon is discharged.

The principal ornament of the place consists in a piece of water, over which a bridge is thrown; at one end of the bridge is an artificial cave fitted up like a lion’s den, the head of a lion cut in stone peeping from the entrance. Above the cave is a pagoda, which forms a summer-house three stories high. At the top is a cistern which is filled by means of a forcing-pump, and which supplies the mischievous fountains already mentioned.

The little insens near the mansion-house are decorated with many small plants of the double pomegranate, sweet bay, laurestinus, and double myrtle, planted in large ornamented flower-pots and in tubs. These plants are all trained with a stem three or four feet high, and with round bushy heads after the manner of pollard willows in English meadows. The appearance produced by a collection of such plants is exceedingly acquired to a more natural mode of training. Eight American ales (Agave Americana), also in huge Dutch flower-pots, finish the decoration of the lawn, and it must be confessed, harmonize very well with the formal evergreens just described. A very good collection of orange-trees in tubs was disposed along the sides of the walks in the flower-garden; two of the myrtle-leaved variety were excellent specimens. All of these were pollarded in the style of the evergreen plants.

The soil of the place, being a mixture of fine vegetable mould, resembling surface peat-earth, with a considerable proportion of white sand, seems naturally congenial to the growth of American shrubs; and,
124. The villa of M. Hopsomere is remarkable for three acres covered with groups of American plants of great size and in the highest degree of luxuriance. An irregular piece of water expands itself among the groups, and forms numerous bays, islets, sinuosities, &c. The surface is generally of turf, but in some places in earth, with edgings of slieath to the walks; the walks are without gravel; and the gardener, as in the other places visited, was wretchedly habitied, without shoes or stockings, and could not read. (Hort. Tour, 1.4.)

125. The seat of Madame Vilain Quatorze (fig. 10.), like most of the others mentioned, and villas in general in this country, is interspersed with water, and the boundary of the demesne, instead of being a wall, hedge, or belt of plantation, is a broad canal, over which of course is seen the adjacent country. The grounds are of considerable extent, and include a farm, pleasure-ground, kitchen and flower garden. A plan of a part of the grounds round the house has been given in the horticultural tour, in which the following objects are indicated:

A hot-house for exotic plants. (a)
An aviary with shrubs for the birds to perch upon. (b)
Gardeiner's room. (c)
Green-house. Entrance by flight of wooden steps. (d)
Stove for exotic plants. (e)
Dry-stove. (f)
Picture-gallery of a considerable height. It has an arched roof, and is lighted from the top. (g)
Dwelling-house. (h)
A large mirror is placed at the end of the passage. Lamps are suspended from the ceilings of the house, gallery, greenhouse, and stoves, at different places. (i)

126. The place of M. Smetz is the finest near Antwerp. It was laid out in 1722 partly in the Dutch and partly in the English taste, and contains at present, scenes of tonsile evergreens, vistas, canals, lakes, secret water-works, caves, tombs, a lawn with a flock of stone sheep, a shepherd and dogs, dwarfs, a drunkard, and other paltry contrivances. There are, however, good span-roofed hot-houses, rustic seats, fine exotic trees, especially the purple beech (which here seeds freely, and comes purple from the seed), catalpa and liquidambar, fine collections of dahlias, asclepias tuberosa, and lilium superbum, in extensive groups; and on the whole "as many natural beauties as can be expected in a flat country, and instances of good taste and judicious management more than counterbalanced by those of the opposite description." (Hort. Tour, 116.)

127. The villa of M. Catsen de Wulfe near Antwerp is remarkable for two elegant curvilinear hot-houses, erected by Messrs. Bailey of London, and glazed with plate glass. Their effect surpasses any thing of the kind on the continent. A rich collection of the choicest exotics has lately been procured from the Hackney nursery.
128. The gardens round Rotterdam are generally many feet below the level of the canal. On the Cingle, a public road which surrounds the city, are, a continued series of garden-houses nearly a mile in extent; these miniature villas (lust hofs) being separated from each other only by wooden partitions, which are generally neatly painted. To these the citizens with their wives retire on Sunday to smoke and talk.co.

(Hort. Tour, &c. 157.)

129. The palace-garden at Haarlem formerly occupied by King Louis, and originally the property of the celebrated banker, Hope, is in no respect remarkable as to design; but pits are grown there better than in most gardens in Holland, and strawberries, ripened within, are successfully forced. The Duke d’Aremberg’s seat near Enghien, like many others in Flanders and Holland, was ruined during the excesses of the French revolution; but the Duke is now restoring it, and has begun with the gardens rather than with the house. Extensive hot-houses are erected and many new fruit-trees planted. The finest part of the garden is the flower-alley, and the state of the celebrated tulip garden is seen from the belvedere before it is entirely planted with the different species of tulips, hyacinths, and narcissus. “This temple is of a heptangular shape, and at the angles on every side are two parallel columns placed about a foot apart. From the large sides proceed as many broad, straight, and long avenues of noble trees, affording rich prospects of this country in all these directions; and from the seven angles, and seen between the columns, proceed an equal number of small and narrow allies, each terminated by some statue, vase, bust, or other ornament. The temple is surrounded by a moat lined with polished marble. The old orange-grove is situated at the end of the avenue. It is one hundred and seventy-five years old, and contains one hundred and eight orange-trees in tubs, many of them, as is the case in different old family-seats of the Netherlands, presents from the kings of Spain 200, 300, and 400 years ago. The trees show straight stems of six or eight feet, and globular heads, from which, according to the age of the trees, pines and blossoms are pinched off as soon as they appear, for culinary and perfumery purposes.

(Hort. Tour, 2d. 372.)

SUBSECT. 2. Dutch gardening, in respect to the Culture of Flowers and Plants of Ornament.

151. The taste for flowers so prevalent in Holland, is thought to have originated with their industry early in the twelfth century, the study of flowers being in some degree necessary, as affording patterns for the ornamental linen and lace manufacturers. Lobel, in his Histoire des Plantes, 1756, states, that the taste for plants existed among the Flemings during the crusades, and under the dukes of Burgundy; that they brought home plants from the Levant, and the two Indies; that exotics were more cultivated there than anywhere else; and that their gardens contained more rare plants than all the rest of Europe besides, till, during the civil wars which desolated this country in the sixteenth century, many of their finest gardens were abandoned or destroyed. Holland, Deleuze observes, had at the end of the seventeenth century, a crowd of distinguished botanists: and was then, as during the century preceding, the country the most devoted to gardening. (Discours sur l’état ancien et moderne de l’Agriculture et de la Botanique dans les Pays Bas, Par Van Hulthem, 1817; Extrait du Discours prononcé, &c., à Gand, par M. Cornelissen, 1817.)

152. The botanical garden of Leyden was begun in 1577, thirty-one years after that of Padua. It was confided to Cluyt, a celebrated botanist, afterwards to Bontius, and in 1592, L’Ecluse, from Frankfort, was appointed professor of botany. In 1599 they constructed a greenhouse, and, in 1633, the catalogue of the garden contained 1104 species. At this time the magistrates, the learned men, and the wealthy citizens were occupied in facilitating the progress of botany, and the introduction of new plants. A ship never left the port of Holland, Deleuze observes, the captain of which was not desired to procure, wherever he put into harbour, seeds and plants. The most distinguished citizens, Verneburg, Favel, Simon de Beaumont, and Rheede, filled their gardens with foreign plants, at great expense, and had a pleasure in communicating those plants to the garden of Leyden. This garden, in Boerhaave’s time, who, when professor of botany there, neglected nothing to augment its riches and reputation, contained (Index alter Plant. 1720) upwards of 6000 plants, species and varieties. Boerhaave here exemplified a principle, which he laid down (Elementa Chemia) for adjusting the slope of the glass of hot-houses, so as to admit the greatest number of the sun’s rays, according to the latitude of the place, &c. These principles were afterwards adopted by Linnaeus at Upsal, and by most of the directors of botanical gardens in Europe. It was in this garden, about the beginning of the eighteenth century, that the geniææ and ficoidæ, and other ornamental exotics were first introduced from the Cape. The garden of Leyden was visited by Sir J. E. Smith in 1786 (Tour, &c. vol. i. p. 11.), who observes, that it had been much enlarged within the last forty years, and was now about as large as the Chelsea garden. In 1814 it appeared rather neglected; many blanks existed in the general collection of hardy plants, and the hot-houses were much out of repair. It contains, however, some curious old specimens of exotics, as Clusius’s palm (Chamerops humilis), twenty feet high, and upwards of 225 years old; a curious ash, and various other trees and shrubs, planted by Clusius. A new garden, in addition to the old one, and a menagerie, are in progress. In this new garden the walks are laid with a mixture of peat-moss and of tanners’ bark reduced to powder. Leyden, Deleuze informs us, was, for more than fifty years, the only city in Holland where there was a botanical garden; but before the middle of the seventeenth century, they were established in all the provinces.

(Hort. Tour, 218.)
134. The garden of Groningen was begun by Henry Munting, a zealous botanist and learned man, who had spent eight years travelling in the different countries of Europe, establishing correspondences between botanists. He spent the greatest part of his fortune in the states of Groningen, thinking so useful an establishment ought to be under the protection of the republic, purchased it, and appointed him professor. The catalogue of this garden, published in 1648, contains about eight thousand plants, without a great many more; 150 of pinks, and 150 of tulips. Henry Munting was succeeded by his son, Abraham, esteemed for his posthumous work, *Phytographia Caroloa.* Both these gardens are still kept up, but without that enthusiastic ardor which distinguished the citizens of Holland, when under more auspicious political circumstances than they are at the present time.

135. The Antwerp garden was formerly one of considerable repute in the Low Countries. In 1579 a catalogue of this garden was given by Dodoneus (*Florum et Coronarium orb., Hist.*) which contained a considerable number of plants, including a great variety of tulips.

136. The garden of Clifford, near Haerlem, of which Linnaeus published the history, was the most celebrated in 1757. Clifford got all the new plants from England, and corresponded with the botanists of every country. Boerhaave gave him the plants of the Leyden garden; Siegesbeck sent him those of Russia; Haller, those of the Alps; and Burman, Roelli, Gronovius, and Miller, sent him portions of the seeds which they received from different parts of the world. This garden had four magnificent hot-houses; one for the plants of the Levant and the south of Europe, one for Africa, one for India, and one for America.

137. The botanical garden of Utrecht was founded in 1630, and contains several palms and other exotics, brought there at that time. It is still kept in tolerable order, but displays no kind of scientific arrangement. (*Hort. Tour, 244.*)

138. The botanic garden of Ghent, established by Buonaparte in 1797, is, in the present day, the richest and best garden of the Netherlands. The area is about three acres; it has a considerable collection of hardy herbaceous plants, arranged after the Linnaean method; a pleasure-ground, in which the trees and shrubs are distributed in natural families, and so as to combine picturesque effect; an excellent rosary, chiefly trained in the tree manner; and a range of hot-houses, in part with glass roofs. In the pleasure-ground the busts of eminent botanists are distributed with good effect; and on the large boxes of palms, and other exotics, are marked the name of the donor, or the year in which the plant or tree was originated, or introduced to the garden. On the whole, it is more complete than any garden we have seen south of the Seine, excepting that of Paris, in 1841.

139. The royal botanic garden of Brussels has a good collection of orange-trees; but in all other respects is of a very inferior description.

140. The private botanic gardens of Van Schenen and Dr. Daaler, at Antwerp, are mentioned with approbation in the *Horticultural Tour.* (p. 121.)

141. The botanic garden of M. Parmentier, mayor of Enghien, is not only the richest in the low countries, but, perhaps, in Europe. In 1817, Neil and his companions considered it as only exceeded in exotics by the collection at Kew, or at Meurs. Loddiges.

142. *Festivals of Flora* are held twice a year, at midsummer and midwinter, by the Agricultural Society of Ghent, and others. The plants are exhibited for three days. "By a pleasing fiction, the plants alone are said to be competitors, and the successful plant is said to be crowned." The reward is an honorary medal. (*Hort. Tour, &c. p. 521.*)

143. Florists' flowers began to be objects of commerce in Holland, about the beginning of the seventeenth century. Double flowers were then first noticed, or brought into repute, which may be said to have created a new era in gardening, and certainly laid the foundation in Holland of a considerable commerce: — the more valuable, as it is totally independent of political or civil changes, and founded on the peculiar qualities of the soil and climate for growing bulbous roots. The florimania, as it is termed by the French, existed in the highest degree among the Dutch, from the beginning to the middle of the seventeenth century. Many noted instances are on record, of the extravagant sums given for flowers possessing certain qualities agreed on by florists as desiderata, and established about this time as canons of beauty. Hirschfeld states, that in the register of the city of Alkmaar, in the year 1637, they sold publicly, for the benefit of the Orphan Hospital, 120 tulips, with their offsets, for 9000 florins; and that one of those flowers, named the Viceroy, was sold for 4203 florins. When we consider the value of money at this remote period, these sums appear enormous, a florin at that time in Holland (*Anderson's History of Commerce*) being the representative of nearly an English bushel of wheat.

144. The commercial flower-gardens or bloomesteries of Haerlem have long been the most celebrated for bulbous-rooted flowers. The name of Van Eden has been noted for upwards of a century; and there are now four gardens occupied by different members of this family, celebrated florists. That of Voorhelm is of equal antiquity and celebrity. Of the gardens of both families, and of several others, accounts will be found in the Horticultural Tour. The most extensive and best managed is said to be that of Schneevoght, lately a partner with Voorhelm.

145. The florimaniasts, Bosc observes, were much more numerous towards the middle of the last century than at this moment (1809). "One does not now hear of twenty thousand florins being given for a tulip; or of a florist depriving himself of his food, in order to increase the number and variety of his anemones, or passing entire days in admiring the colours of a ranunculus, the grandeur of a hyacinth, or trembling, lest the breath of an over-curious admirer should hurt the bloom of an auricula." The general price of choice bulbs now, it is observed in the *Horticultural Tour,* varies from three to ten guineas (a bulb. = ls. 8d.); a few kinds are valued at from ten to twenty guineas; and the most select, new, and consequently rare, varieties, seldom fetch more than from twenty to 50 guineas. Among the most precious at this time are, the Universal Conqueror, Pompe Funicere, and Charbonier Noir, with yellow grounds; Louis XVI. and Toilette Supérieure, with white grounds, and the price of them is one hundred guineas (£8 2s. 6d.) a bulb. (*Hort. Tour, p. 195.*)
146. The Dutch and Flemings are eminent as fruit-gardeners, but, as Harte observes, they are better operators than writers, and having at the same time a good deal of the spirit of *gens de métier*, we have almost nothing to offer in the way of historical information. Those gardens, which Gesner and Stephanus inform us were so richly stocked with flowers early in the sixteenth century, would, no doubt, be equally so with fruits and legumes. One of the earliest books on the horticulture of the Low Countries, is that of Van Osten, published about the end of the seventeenth century. They appear at that time to have had all the fruits, now in common cultivation, in considerable variety, excepting the pine-apple, which Miller informs us was introduced about that time by Le Cour, of Leyden, from the West Indies, although not mentioned by Van Osten or Comelin. It is generally said, that about the same period all the courts in Europe were supplied with early fruits from Holland. Bénard admits (quoted in *Repertory of Arts*, 1802) that this was the case with the court of France, so late as the reign of Louis the Fourteenth. Miller informs us that Le Cour paid great attention to gardening, and especially to the culture of wall-fruits, and that he tried the effects of different kinds of walls and modes of training. Speechly, early in the eighteenth century, made a tour in that country, chiefly to observe the Dutch mode of cultivating the pine and the grape; they forced, he informs us (*Tr. on the Vine*), chiefly in pits and low houses, and produced ripe grapes of the sweet-water kind in March and April. The Low Countries are celebrated for good varieties of the apple and pear. The supplies of these articles sent to the markets of Brussels, Antwerp, and Amsterdam, are equal, if not beyond any thing of the kind to be met with elsewhere in Europe. The climate of Flanders suits these fruits; that of Holland is rather adverse to flavor, from its moisture; but peaches, pines, and melons attain a larger size than in France. Tournay is so much celebrated for its pears, that the Ghent Society, in 1816, offered a prize for "the best explanation of the causes of the superiority in size, beauty, and flavor, of the pears grown at Tournay." (*Hort. Tour*, 338.) Forcing in pits and frames, is carried to great perfection in Holland, and melons and pines are, at the present time, sent to the London and Paris markets, and sold for very moderate prices.

147. The culinary vegetables of Holland are brought to great perfection. All the plants of culture, and especially the cabbage tribe, turnip, onion, carrot, &c. are grown to a large size, and very succulent. Of plants edible in their natural state, as the parsley and other herbs, and the fungi, they have excellent varieties. For leguminous crops the climate is sometimes too moist. Brussels is noted for the greens or sprouts, which bear the name of that town; and Van Mons informs us (*Hort. Trans.* iii. 197.) that they are mentioned in the market regulations of that city so early as 1213. The Caledonian Tourists, in 1817, found the markets of Ghent and Amsterdam better supplied with culinary vegetables than any in Holland. The cauliflower was excellent. The Dutch also excel in asparagus, carrots, and purslane.

148. Forcing-houses have been long in use in Holland, but the date of their introduction we have not been able to learn. It is singular that they are not once mentioned in the early editions of Van Osten, published from 1689 to 1750; but Adanson (*Familles des Plantes, Preface*) writing about the latter period, speaks of the hot-houses of the Dutch in terms which evidently refer to forcing-houses. Orangeries, and botanic houses, we have seen, (132.) were in use so early as 1599. Within the last twenty years the demand for forced productions has greatly diminished in Holland. Summer, or what are called main crops, are now chiefly attempted, both in public and private gardens; but after the annexation of Holland to France, and since its subsequent union with Flanders, the spirit for enjoyments of even this sort, has declined with the means of procuring them.

149. Planting is not very general in Holland. In a country so thickly peopled, and so conveniently situated in respect to marine commerce, it is not likely that much ground would be devoted to merely useful plantations. In the more inland parts of Flanders, there are natural forests and extensivecopes; these have been, and continue to be kept up, and in some cases increased in extent by planting land too poor for cultivation. In Radcliff's Agricultural Survey of that country, some account will be found of their management. We observed, in 1819, some belts and clumps forcing, in the English manner, on some waste lands near Cambray, and that the Duke of Wellington was planting on his estate at Waterloo. Between Aranagoe and Rheenen, a tract of land, several miles in extent, and no better in quality than Bagshot-heath, is planted with Scotch firs, Weymouth pines, beech, and birch; and many hundred acres adjoining have been sown with acorns for cope, and enclosed with thorn hedges.

150. *Avenues*, *hedge-rows*, and *exter-kelts*, are the principal plantations of the Dutch. In these they excel, and the country in consequence resembles a series of gardens.
Avenue trees, chiefly elms and oaks, are trained for eight or ten years in the nursery; repeatedly removed so as to become furnished with numerous fibrous roots, and pruned so as to have clean smooth stems from ten to fifteen feet high. Avenues, being public property, are under the care of proper officers. Judging from the vigorous growth of the trees, and the manner in which they are pruned, these officers seem to understand their business, and to do their duty. In Rotterdam, on the quays, are perhaps the finest trees in Holland; they are narrow-leaved elms, upwards of fifty feet high, with clear stems of twenty-five feet, and upwards, of a century old. At the Hague are remarkably fine limes in the Mall, on the road to Scheveling; and oaks, elms, and beeches, round the palace called the House in the Wood. The hornbeam is a very common plant for the garden-hedges. Every plant in the row or hedge is trained with an upright stem, and the side shoots are shorn so closely, that we often find hedges of six or eight feet high, not more than eighteen inches wide at base, contracted to six inches wide at top. These hedges receive their summer shearing in July, by which time scarlet runners are ready to shoot up from the garden side of their base, which, in the course of two months, cover the hedge with their fresh verdure and brilliant blossoms, and present a good crop in October and the beginning of November. The Dutch have also very excellent field-hedges of birch and willow, as well as of all the usual hedge-plants, and the gardeners are particularly dexterous at cutting, training, and shearing them. The deep moist grounds on the banks of their estuaries are particularly favorable for the growth of the willow, and the hoops of two years' growth from the Dutch willow (a variety of Salix alba, with a brownish bark,) are in great esteem in commerce. Their common basket willows (S. viminalis) are also excellent.

**Subject. 5. Dutch Gardening, as empirically practiced.**

151. *Happily the use of gardens is universal in the Netherlands; and of the Dutch and Flemings it may be truly said in the words of Lord Temple, "that gardening has been the common favorite of public and private men; a pleasure of the greatest, and a care of the meanest, and indeed an employment and a possession, for which no man there has is too high nor too low."* The gardens of the cottagers in these countries are undoubtedly better managed and more productive than those of any other country; no man who has a cottage is without a garden attached; often small, but rendered useful to a poor family by the high degree of culture given to it. Every available particle of matter capable of acting as manure is assiduously collected, and thrown into a neat ridge, cone, or bed, which is turned over frequently; and when sufficiently fermented and ameliorated, applied to the soil. The plants in general cultivation in the cottage-gardens are the cabbage tribe, including Brussels sprouts, the white beet for the leaves and stalks, the parsnip, carrot, yellow and white turnip, potatoe, the pea, bean, and kidney-bean; the apple, pear, and currant, and in some places, the vine trained over the cottage, are the fruits; and double stocks, rockets, wall-flowers, pinks, violets, roses, and honey-suckles, the leading flowers and plants of ornament. It is almost unnecessary to add, that the gardens of the tradesmen, farmers, citizens, private gentlemen, and princes, rise in gradation, in extent, riches, and high keeping.

152. *The principal nurseries, florists' gardens, and market-gardens are in the neighbourhood of Amsterdam, Haerlem, and Antwerp. These gardens formerly supplied trained trees, vines, and all the most valuable plants to Britain, and other parts of Europe; and the florists still continue to monopolise the commerce of bulbous roots. Great part of the fruit-trees sent by London and Wise from their nursery at Brompton Park, in the beginning of the 18th century, were previously imported from Holland; many of them reared in large wicker-baskets, were sent over in that state, and produced fruit the first year after final planting. Justice (Brit. Gard. Dir.) gives credit to the Dutch nurserymen for accuracy and punctuality; he mentions Voerhelms and Van Zompel as tradesmen which he could recommend; and it is remarkable, that the same establishment (Voorein and Schneevooght) is the most eminent at this day. Garden seeds, for which Holland has long been celebrated, are chiefly grown by the market-gardeners and small farmers round Haerlem. Roses are extensively grown in Noordwyck, between Leyden and Haerlem, for the apothecaries, and the dried leaves are sent to Amsterdam and Constantinople. The sorts are, the Dutch 100-leaved and the common cabbage rose. A striking characteristic of Dutch fruit and forest tree nurseries is the length of time the trees are trained in the nursery. They are so often removed there, as to have a large fasciculus of fibrous roots, and the fruit-trees commonly bear for a year or two before they are sold, at least for local planting. Ready-grown hedges and shrubs, of various sizes and shapes, may be purchased, and as they have been transplanted every third year, like the trees, there is little risk of their not succeeding. At Brussels, professor Van Mons has established a fruit-tree nursery, which he calls *Pepiniere de la Fidelite*, in which are grown upwards of 800 new varieties of pear, raised by himself and M. Duquesne of Mons, since 1803, besides new varieties of the other hardy fruit-trees.
Book I.

GARDENING IN FRANCE.

153. The operative gardeners in Holland are for the most part apprenticed, and serve as journeymen before they are employed to undertake the care of gardens where several hands are employed; but so general is horticultural knowledge, that every labourer is considered as capable of cropping and dressing an ordinary tradesman or farmer’s garden. 154. There are few or no artist-gardeners in Holland. Eminent practical gardeners are employed to lay out walled kitchen-gardens; and artists from Paris, generally called in to lay out parks or pleasure-grounds of more than ordinary extent.

Subsect. 6. Dutch Gardening, as a Science, and in respect to the Authors it has produced.

155. Horticulture as a science, has been less cultivated in the Netherlands than in Italy or France. The botanists of the country were not among the first to advance the study of physiology, nor has any of their practical men appeared with the science of a Quinteiny or a Miller. “The patience and riches,” Bosc observes, “which produced so high a degree of florismana in Holland, might have been usefully employed in advancing vegetable physiology; but science owes nothing to the Dutch in this branch.” At the present time, when science is so rapidly and so universally spread, the learned in the Netherlands are unquestionably on a footing with those of other countries; a proof of which may be derived from the remarks of Van Mons, Van Marum, and other Dutch and Flemish correspondents of our Horticultural and Linnaean Societies. The majority of working gardeners may be considered as nearly on a par with those of this country in point of science, and before them in various points of practice.

156. The Dutch and Flemings have few authors on gardening, and the reason may be, the universality of practical knowledge in that country. Commelin and Van Osten are their principal authors. The former published the Hortus Amsterdamus, in 2 vols. folio, in 1697, and subsequently a small work on orange-trees; and Van Osten, who was gardener at Leyden, published his Dutch Gardener about 1710. Various French works on gardening have been printed at the Hague, and other parts of Holland.

Sect. III. Of the Rise, Progress, and present State of Gardening in France.

157. Three eras mark the gardening of France; that of Charlemagne, in the eighth; of Louis XIV., in the middle of the seventeenth; and that of the Revolution, at the end of the eighteenth centuries. The first introduced the best fruits, and spread the use of vineyards and orchards; the second was marked by splendor in design; and the third by increased botanical and scientific knowledge.

Subsect. 1. French Gardening, as an Art of Design and Taste.

158. Though the gardening of Charlemagne in the eighth century was chiefly of the useful kind, yet he is said (see Nigellus) to have had a noble palace at Ingleheim, on the Rhine, supported by a hundred columns of Italian marble. This could hardly be erected, without an accompanying and decorative garden, though the frugal habits of that prince might prevent an extravagant display of design. From the Hortulus of Walafird, published in the beginning of the ninth century, it appears that gardens were in these times made only within the walls of castles and monasteries.

159. Previously to the sixteenth century, any notices of gardening in France chiefly relate to other branches than that under consideration. At the end of this century, Francis the First built the palace of Fontainbleau, and introduced there some traits of the gardening of Italy. Stephens and Liebault published their Maison Rustique about this time; the early editions contain little on the subject of design, farther than directions for forming avenues, arbors, and flower-gardens.

160. In the beginning of the seventeenth century, Hirschfield observes, the gardens of France consisted only of a few trees and flowers, some plots of turf, and pieces of water; the whole, he adds, according to their own accounts, “totally deprived of taste, and completely wild and neglected.”

161. About the middle of the seventeenth century, and in the second year of Louis the Fourteenth’s reign, France was visited by Evelyn, who makes the following remarks on the gardens in and near Paris:

The garden of the Tuileries “is rarely contrived for privacy, shade, or company, by groves, plantations of tall trees, especially that in the middle, being of elms, and another of mulberries. There is a labyrinth of cypress, noble hedges of pomegranates, fountains, fish-ponds, and an aviary. There is an artificial echo, redoubling the words distinctly, and it is never without some fair nymph singing to it. Standing at one of the focuses, which is under a tree, or little cabinet of hedges, the voice seems to descend from the clouds; at another, as if it were under ground. This being at the bottom of the garden, we were let into another, which, being kept with all imaginable accurateness as to the oranger, precious shrubs, and rare fruits, seemed a Paradise.”

St. Germaines en Lay. “By the way I aighted at St. Cleez, where, on an eminence near the river, the archbishop of Paris has a garden, for the house is not very considerable, newly watered, and furnished with statues, fountains, and groves; the walks are very fine; the fountain of Lacoon is in a large square pool throwing the water near forty feet high, and having about it a multitude of statues and basins, and is a surprising object; but nothing is more esteemed than the cascade, falling from the great steps into
the longest and largest walk from the Mount Parnassus, which consists of a groto, or shell house, on the summit of the hill, wherein are divers waterworks, and conveniences to wet the spectators.

Cardinal Richelieu's villa at Rueil. "The house is small, but fairly built in form of a castle, moated round. The offices are towards the road, and over-against them are large vineyards walled in. Though the greatest size of it, the gardens show us that Italy has any exceeding it for varieties of pleasure. The garden nearest the pavilion is a parterre, having in the midst divers statues, perpetually spouting water into an ample basin, with other figures of the same metal; but what most is admirable is the vast enclosure, and a variety of ground in the large garden composed of terraces, whereas some (of perrenial greenes, groves, and walks of great length, so accurately and kept cultivated, that nothing can be more agreeable. On one of these walks, within a square of tall trees, is a basaill of copper, which, managed by the fountaineer, casts water near six square cubits, or itself, the water falling in a groto. This leads to the Citroniere where is a noble conserve of all these rarities; and at the end of it is the arch of Constante, painted on a wall in oil, as large as the real one at Rome, so well done, that even a man skill'd in painting may mistake it for stone and sculpture. The sky and hills, which seem to be between the arches, are the drawers of the grove, and the shadows of the groves, thickening themselves against the wall. At the farther part of this walk is that plentiful, though artificial, cascade, which rolls down a very steep declivity, and over the marble steps and basins, with an astonishning noise and fury; each basin hath a jet of water, which, falling in sheets of transparent glass, is thrown back and lead, from whence it glides silently down a channel, through the middle of a spacious gravel-walk, terminating in a groto. Here are also fountains that cast water to a great height, and large ponds, two of which have islands for harbour of fowls, of which there is store. One of these islands has a receptacle for them, built of vast pieces of rock, set in the highest part, and shaped to receive water out over with moss, ivy, &c. This leads to another grove, with tall trees; in this the fowls lay eggs and breed. We then saw a large and very rare groto of shell-work, in the shape of satyrs, and other wild fancies; in the middle stands a marble table, on which a fountain plays in form of glasses, cups, crosses, fans, crowns, &c. Then the fountaineers represent a shower of rain, from the top, met by small jets from below. At going out, two extravagant musketeers shot us with a stream of water from their musket-barrels. Before this groto is a long pool, into which ran divers spouts of water from leaden escapoy basins. The viewing this Paradise made us late at St. Germaines.

The first building in the garden is that of Gustavus, which true virtuoso made it complete. Speaking as to the style of magnificence then in fashion, which was so great a mixture of the Gothic, as may be seen of what there is remaining of his in the old castle, an irregular piece as built on the old foundation, and having a moat about it. It has yet some spacious and handsome pavilions, and a chapel, and a large state room, finished by the Prince Louis, at this building, by a court, of a lower but more modern design, built by Henry IV. To this belong six terraces, built of brick and stone, descending in cascades, towards the river, cut out of the natural hill, having under them several beautiful pavilions; of which four have windows, and several objects, in the manner of scenes, and other motions by force of water, shown by the light of torches only; amongst these is Orpheus, with his music, and the animals which dance after his harp; in the second, is the king and dolphin (dauphin); in the third is Neptune sounding his Trumpet, his chariot drawn by sea-horses; in the fourth is Minerva, and her chariot, with horses, and other mermaids and happy fishermen, and many other devices. There is also a dry groto to refresh in, all having a fine prospect towards the river, and the goodly country about it, especially the forest. At the bottom is a parterre; the upper terraces half a mile in length, with double declivities, arched and balustrated with stone of vast and royal cost. In the pavilion of the new castle are many fair rooms well painted, and leading into a very noble garden and park, where there is a small-palace, in the midst of which, on one of the sides, is a chapel with a stone cupola, though small, yet of a handsome order of architecture. Out of the park you go into the forest, which, being very large, is stored with deer, wild boars, wolves, and other wild game. The Tennis-court, and Cavallerizzo for the managed horses, are also very observable.

The Count de Liancourt's palace, in the rue de Seine, "is well-built. Towards his study and bed-chamber joins a little garden, which, though very narrow, by the addition of a well-painted perspective, is to appear greatly enlarged; to this there is another part, supported by arches, in which runs a stream of water, rising in the aviary, out of a statue, and seeming to flow for some miles, by being artificially continued in the painting, where it sinks down at the wall. It is a very agreeable deception. At this garden there is a little theatre, made to give place to several figures of men and women, painted on light boards, and cut out, are by a person who stands underneath, made to act as if they were speaking, by guiding them, and reciting words, in different tones, as the parts require, &c.

A pretty garden at Caen, "planted with hedges of alaternus, having at the entrance a screen of an exceeding height, accurately cut in topiary work."

The gardens of the Luxembourg are near an English mile in circumference. "The parterre is, indeed, of the most regular dress, that can be possibly imagined, kept under the care of a man whose profession is it, with the lodgings which front it. The walks are exactly fair, long, and variously descending, and so justly planted with limes, elms, and other trees, that nothing can be more delicious, especially that of the horn-beam hedge; which, being high and stately, butts full on the fountain." (Memoirs, vol. i. 40-52)

And St. Germaines, "between St. Germaines and Sceaux, is a very fine park, where the Loose is environed by a dry moat; the offices undergroun; the gardens are very excellent, with extraordinary long walks, set with elms, and a noble prospect towards the forest, and on the Seine towards Paris. Take it altogether, the meadows are most truly beautiful, the cornfields, orchards, and vineyards, I hardly saw any thing in Italy to exceed it. The iron gates are very magnificent." (Memoirs, p. 259.)

162. The French taste in laying out gardens may be considered as having been settled and confirmed by Le Notre during the reign of Louis XIV. Le Notre's taste and style, Daines Barrington observes, continued in full repute for upwards of a century; and appears to have been in general vogue so late as 1771, fifty years after the introduction of the modern style in England. However remarkable this may appear, it is a fact which does not admit of a doubt; for Millin, the editor of the Journal Encyclopédique, in a critique on the translation of Wheatley's Observations on Modern Gardening, published that year, after the most liberal encomiums on the work, expresses his doubts as to how the modern style would be received in France, where he adds, "Le Notre's school is still followed, and every rich proprietor is anxious that his garden, if it does not resemble, shall at least recall to his mind those of the court, at Versailles, Trianon, Meudon, Sceaux, or Clagny."

163. Le Notre was the most celebrated gardener that probably ever existed. If Le Notre, observes Hirschfield, had been born under any other monarch than Louis the XIV., his taste, would, in all probability, never have spread, or his name been known to posterity. But that age, in which a feeling for the fine arts had begun to awake in men's minds,
together with the personal character of this monarch, was favorable to pomp and brilliancy. The nation and the court wished to be dazzled and enchanted by novelty and singularity; and though there certainly was nothing in Le Notre's manner that had not been before displayed in France and Italy, and with the exception of parterres, even by the Romans, yet the grand scale and sumptuous expense of the plans surpassed every thing before seen in France, and produced precisely the desired end. His long clipt alleys, triumphal arches, richly decorated and highly wrought parterres; his fountains and cascades, with their grotesque and strange ornaments; his groves, full of architecture and gilt trelisses; his profusion of statues and therns; all these wonders springing up in a desert-looking open country, dazzled and enchanted every class of observers. Le Notre was educated an architect, and had attained his fortieth year before he finished his first work in the rural department of his profession, the garden of Vaux le Vicomte, afterwards V. le Villars, and now (1823) Vaux Praslin. The king, enchanted with this decoration, made Le Notre his controller-general of buildings and director of gardens, loaded him with presents, gave him a patent of nobility, and made him Knight of the order of Saint Michael. His principal works are Versailles, which cost nearly 200 millions of francs; Trianon, Meudon, Saint Cloud, Seaux, Chantilly, and the celebrated terrace of Saint Germins. The gardens of the Tuilleries, the Champs Elysées, and many others were either formed by him or improved from his designs. In 1678 he went to Italy, where he furnished the plans of several gardens, particularly those of the villas Pamphili and Ludovisi. England, Sweden, and all Europe adopted his manner. He died in 1700. (Hirschfield, tom. v. 298.)

164. The gardens of Versailles, the grand effort of Le Notre, have been so frequently described, and are so generally known, that we shall only quote one or two opinions concerning them. Hirschfield considers them not as models of taste, but as models of a particular class or character of gardens. Gray the poet was struck with their splendor when filled with company, and when the water-works were in full action. Lord Kaines says they would tempt one to believe that nature was below the notice of a great monarch, and therefore monsters must be created for him as being more astonishing productions. Bradley says, "Versailles is the sum of every thing that has been done in gardening." Agricola, a German author, declares (Phil. Treat. on Agr. Trans. by Bradley,) that the sight of Versailles gave him a foretaste of Paradise. Our opinion coincides with Gray's: "Such symmetry," as Lord Byron observes, "is not for solitude." During the Revolution, it was proposed that the palace and gardens should be sold as national property; but M. Le Roy, the architect, greatly to his honor, stepped forward and represented that the palace might be usefully employed for public purposes, and the garden rendered productive of food for the people. "This satisfied the citizens: a military school was established in the palace; and by planting some of the parterres with apple-trees, and others with potatoes, the garden was saved." Niell was informed, that by calculation the water-works of Versailles, which are not played off often than eight or ten times a-year, cost 200l. per hour. There is an orange-tree here "sémo in 1421," and thirty feet high. (Hort. Tour, 409. et seq.)

165. Le Notre's successor was Dufresnoy, controller of buildings; his taste differed considerably from that of his predecessor, and he is said to have determined on inventing a style different and more picturesque. He preferred unequal surfaces, and sometimes attempted these by art. His style had something of the modern English manner, but his projects were rarely carried into execution. He was accused of being too expensive; but it is more probable that the chief objection to his taste was the continued prevalence of that of his predecessor. However, he constructed, in a style superior to that of Le Notre, the gardens of the Abbé Pajot, near Vincennes, and in the Faubourg Saint Antoine, two other gardens of his own, now known under the names of Moulin, and of Chemincreux. Marly has been erroneously attributed to Dufresnoy, but it was constructed from the plans of the architect Drusé, controller of the works at St. Germins. The garden of Bagnolet is the principal work of Desgodetz, a relation of Le Notre. Chapelle d'Isle and the brothers Mansard, and other architects, at that time constructed several gardens in France, but on the general plan of that of Le Notre. Millin considers Dufresnoy as an artist of much greater genius than Le Notre, and more attached to natural beauties, though less known by his talent for designing gardens than by his comedies.

166. The English style of gardening began to pass into France, after the peace of 1762, and was soon afterwards pursued with the utmost enthusiasm. Hirschfield affirms that they set about destroying the ancient gardens, and replanting them in the English manner, with a warmth more common to the mania of imitation than the genius of invention. Even a part of the gardens of Versailles were removed, as De Lille lament (Les Jardins, 4th edit. p. 40.), to make way for a young plantation à l'Angloise. Dufresnoy, as we have already stated, had been bold enough to depart from the former style, and Gabriel Thouin, in the preface to his Plans Raisonnés des Jardins, &c. (1818)
says, this artist gave the model of natural gardens on a piece of ground which belonged to him in the Faubourg Saint Antoine, already alluded to, and thus fixed the principles of natural (that is, English) gardening in France about the commencement of the last century. Laugier is the first French author who espoused the English style of gardening in his Essai sur l'Architecture, published in 1753; and next in order Prevôt, in his Homme du Goût, published in 1770. About the same time, the first notable example was preparing at Ermenonville, the seat of Viscount Girardin, about ten leagues from Paris. An account of this place was written by Girardin himself in 1775, and published in 1777. It was soon after translated into English by D. Malthus, Esq. and is well known for its eloquent descriptions of romantic and picturesque scenes. Morel observes, in his Théorie des Jardins, published in 1766, that very little had been done previously to 1766: he mentions Ermenonville, as to which he had been consulted, and the Duc d'Aumont's park at Guiscard, and a seat near Château Thierry, chiefly laid out by him. Soon after Morel's work, Delille's celebrated poem, (Les Jardins) made its appearance, and is perhaps a more unexceptionable performance than The English Garden of Mason. The French, indeed, have written much better on gardening and agriculture than they have practised,—a circumstance which may be accounted for, from the general concentration of wealth and talent in the capital, where books are more frequent than examples; and of professional reputation in that country, depending more on what a man has written, than on what he has done. It does not appear that English gardening was ever at all noticed by the court of France.

167. Ermenonville (fig.11,) still in the Girardin family, but now rather neglected, appears to have been laid out in a chaste and picturesque style, and in this respect to have been somewhat different and superior to contemporary English places. The château (a) was placed on an island in the lake, near the village (b). Among other objects in the grounds were Rousseau's cottage (c); his tomb in the Island of Poplars (d); that of the landscape-painter Mahier, who had assisted Girardin in designing the improvements in an adjoining island (e); a garden in ruins (f), and the grand cascade (g). Useless buildings were in a great degree avoided, and the picturesque effect of every object carefully considered, not in exclusion of, but in connection with their utility. There is hardly an exceptionable principle, or even direction referring to landscape-gardening laid down in the course of Girardin's Essay; and in all that relates to the picturesque, it is remarkable how exactly it corresponds with the ideas of Price. Girardin, high in military rank, had previously visited every part of Europe, and paid particular attention to England, and before publishing his work, he had the advantage of consulting those of Wheatley, Shenstone, G. Mason, and Chambers, from the first of which he has occasionally borrowed. He professes, however, that his object is neither to create English gardens, nor Chinese gardens, and less to divide his grounds into pleasure-grounds, parks, or ridings, than to produce interesting landscapes, "paysages intéressans," &c. He received the professional aid of J. M. Morel, the Kent of France, who afterwards published Théorie des Jardins, and probably that of his guest Rousseau, who seems to have composed the advertisement to his book. Magellan, in the Gazette Littéraire de l'Europe for 1778, in giving some account of the last days of Rousseau, who died at Ermenonville, and was buried in the Island of Poplars (d) there, informs us, that Girardin kept a band of musicians, who constantly perambulated the grounds making concerts sometimes in the woods, and at other times on the waters, and in scenes calculated for particular seasons, so as to draw the attention of visitors to them at the proper time. At night they returned to the house, and performed in a room adjoining the hall of company. Madame Girardin and her daughters were clothed in common brown stuff, en amazones, with black hats, while the young men wore "habilements le plus simple et le plus propret à les faire confondre avec les enfants du campagnards," &c.
168. *Watelet's garden*, the *Moulin foli*, the next example of the English style in France, is of a very different description from Ermenonville. Watelet is the author of an *Essai sur les Jardins*, which appeared in 1774. His garden was situated in the suburbs of Paris, on the Seine, and contained about four acres, varied by buildings, groves, temples, and inscriptions, and was, on the whole, more in the Chinese style than in that of Kent or Scheemaecker. The author, who professes to take utility for the basis of his art, seems to have felt something wanting, in this particular, to his temples and altars, and is ridiculed by Hirschfeld (*Théorie des Jardins*, tom. i. p. 168.) for proposing occasionally "*de faire périr autant de temples, et les... que faire une troupe de pamphlétariens, valeur qu'aucun de ces autels n'en séduira, faisant des sacrifices, allant porter des offrandes,*" &c. The Prince de Ligne admired Watelet's garden almost as much as that of Girardin, though in so different a style. After describing it, he says, "*Allez-y, incroyables... Méditez sur les inscriptions que le goût y a dites. Méditez aussi sur le plan de Watelet.*" (*Mémoires de...* tom. iv. p. 149.) The object of such an attempt English gardening in France on a small scale is still more to imitate the garden of Watelet, than the "*paysages intéressans*" of Girardin.

169. Of other English or mixed gardens which existed before the Revolution, the garden of Moureau, the property of the Duke of Orleans, was laid out by Blaikey, a British landscape-gardener resident in France, in a romantic and irregular style. Blaikey also formed some scenes in the Petit Trianon, especially in the lower part of the grounds, now occupied by ruins, water, and a cottage, and in their kind very picturesque. It was here that the queen of Louis XVI. used to entertain her guests habited as a shepherdess; that the citizens used to hold *fêtes champêtres* during the Revolution; and that Napoleon made a residence for Maria Louisa. Having reverted to the Bourbons, it is now comparatively neglected and dilapidated. (*Hort. Tour, 406.*) Bugnet, in the Bois de Bologne, formerly the retreat of Count d'Artois, and the Duke of Orleans's park at Rainey, were laid out, in 1779, in the same taste, and by the same artist. The *Jardin de Marbreux* was planted by the Chevalier Jansin, an Englishman. (*Ed. Encyc. xii. 543.*) De Lile cites the gardens of Beleil, the château of the Prince de Ligne. Montreuil, a garden of the Princess Gremene; Maupertuis, a garden of the Marquis de Montesquieu, with a beautifully varied surface, abundance of wood and water, and a desert after the manner of Moreville. He mentions several others, all of which are figured in *Recueil des Jardins*, 16 cahiers, folio, and most of them described by Hirschfeld (*tom. i. & v.*), who considers Moreville and Ermenonville, as the two best specimens of English gardening in France.

*Mereville*, the seat of M. La Borde, was one of the most considerable in France, and was laid out immediately before the Revolution under the guidance of Robert, a famous landscape-painter. The château stood on a terrace, and commanded a distant prospect over a marsh originally of little interest. But the wall of this terrace was covered with artificial rock-work, a river formed in the marsh with a bridge and cascade. The general surface was raised by earth, and on the right and left of the view from the house were raised considerable hills of earth, the one surmounted by a column 193 feet high, serving as a prospect-tower, and the other by a Doric temple of 17 columns. At the base of one hill was a magnificent grove of trees and rocks, and near the other stables in the character of Gothic ruins. Various buildings were erected in other parts of the grounds; one to the memory of Captain Cook, and another to that of M. Laborde's two sons, who perished in the voyage of La Proueuse. Every hardy exotic tree was planted, and many of them, as the tulip-tree, ailanthus, sophora, &c. grew with great vigor and flowered luxuriantly. Many millions of francs were expended on this place, which for some years past has been falling into decay and has been lately sold in lots.

One of the finest modern parks in France is that of D'Argenson near Vienne. Mathews (*Diary of an Invalid*) considered it superior to any thing of the kind he had seen in France or Italy, and says it reminded him of his native Wye, and its picturesque banks.

170. English gardening during the consulate was little attended to. Malmaison, the residence of Josephine, was laid out avowedly in the English style by Morel, and greatly altered and improved by Blaikie and the English resident gardener, Hudson; and richly stocked with trees and shrubs from London. Since that time little has been done on an extended plan; and one may travel from one extremity of the kingdom to the other, without seeing any scene having the general external appearance of an English park. The works of this kind which are executed, are on a very limited scale, and crowded with walks and ornaments. Most of them may be called fanciful, ingenious, and pretty, but few are simple and grand. (*Dulauire Desc. des Env. de Paris, and Hort. Tour, 357. et seq.*) All that a Frenchman considers necessary to form a *Jardin Anglais*, Blaikie states to us, is crooked walks. Blaikie went to France in 1776, remained there during the Revolution, and has been employed by all parties. The directory employed him to plant the Tuilleries with potatoes, and never paid him for the sets; and the national assembly in 1792, appointed him commissioner for the establishment of a botanic garden at Versailles, but he declined the employment. This venerable artist is still employed in all the eminent cases in France, Holland, and the south of Germany.

171. The French revolution, however favorable to the progress of society, by the emancipation of energies and intellects, and by the general subdivision and distribution of property, has, as was to be expected, been injurious to gardening as an art of design; but if once the nation were politically content, a few years of quiet and prosperity, by enriching some and impoverishing others, would end in grouping property in more unequal masses; and the superfluous wealth of the opulent would be employed as before, under the advantages of much more skill to display, and taste to approve what is beautiful or excellent.
172. With regard to the present state of landscape-gardening in France, the royal gardens, the Tuileries, Versailles, St. Cloud, and the Trianons, are still kept up in a respectable style. Ermenonville is in possession of the son of its creator, who, being friendly to the Buonaparte family, was made a president during the reign of a hundred days, and is consequently at present not in favor at court. The grounds are still shown to strangers, but their effect, and the order in which they are kept, are far inferior to what one is led to expect from the description in the Essai sur la Composition des Paysages, &c. and from what, as we were informed (in 1813, and again in 1819), actually was the case half a century ago. We saw no reason to admire the turf, which Sir J. E. Smith informs us (Tour, &c.) had been, in 1786, about two years under the care of an intelligent Scotch gardener, and who, he says, “assured us, and indeed what we saw confirmed it, that the superior beauty of our British grass-plots to those of other countries is principally owing to management, and not to soil and climate.” The lawns of Girardin, and of the king in the gardens we have enumerated, are, we fear, sad proofs of the fallacy of this gardener’s opinion, and of the unsuitableness of dry arenaceous soils and warm climates for those “velvet lawns” which are at once the greatest beauty and the characteristic of English gardening in England. The finest lawns in and around Paris are watered every summer evening, when it has not rained during the day, e.g. that of the Palais Royal.

173. In the neighbourhood of Paris are various Chinese and English gardens which might be mentioned; what they call Chinese gardens differ from their English or (as G. Thouin calls them,) natural gardens, in being still more frittered down by walks, and ornamented by Chinese-looking ornaments. One of the prettiest town-gardens in France, and which it is but justice to say, is unequalled by any of the kind in Britain, is that of Boursan, in Paris, (Rue Mont Blanc,) about an acre in extent. It is described at length in the Horticultural Tour.

174. Near Lyons is Hermitage, a villa of Guilliard St. Etienne, much spoken of in the guides, and by French tourists. It is of small extent, on the rocky embraeuse banks of the Saone, and thickly set with statues, busts, rustic seats (fig. 12), and every sort of garden ornament, with a museum. It is much too theatrical for a garden, and gives more the idea of whim in the proprietor than of any thing else. A situation of so much natural beauty, required at the utmost, only so much art as was sufficient to mark its appropriation by man.

175. Around Montpellier and Marseilles, there is nothing in the way of landscape gardening worth mentioning.

176. The plan of the residence of General Lomet at Agen (fig. 13) is given by Kraft. (Plans de plus beaux jardins, &c. pl. 17.) It is situated on a hilly spot bordering the river, and contains in a very small space a dwelling-house (a), poultry-yard (b), in the pavilions of which (c, d) are the coach-houses, stables, rooms above for the coachman and stable-boys, and the gardener. There is a green-house (c), cart-shed, and warehouse, let off to townsmen (f), a flower-garden (g), principal entrance and avenue (h, i), temple of Flora (k), Roman temple and lath (l), terrace covered with an arbour (m), a vine plantation trained on an arcade trellis in the Italian manner (o), a terrace for orange-trees with a green-house underneath (o), parterre (p), miniature fields of barley, wheat, beans, &c. (q), kitchen-garden (r), numerous monuments and statues (s, t), an orchard (o), and a lake (u). Kraft says, it contains the greatest variety of picturesque views, but has
rather too many winding walks. It was laid out by the architect, Kleber, who afterwards became the celebrated general of that name, and was murdered by a mameluke in Egypt. Kleber seems to have been fond of rustic buildings, with which this garden abounds in the greatest variety of form and dimensions, from the gardener's house, to that of the bees, and the shelter for peacocks.

177. There is a very pleasing English garden at Vitry, the property of Citizen Wenner, in which as much is made of a small spot as can well be done. It was laid out by Charpentier already mentioned.

178. The garden of the postmaster at Altkirch (fig. 14.), in Alsatis, is described by Kraft as a singularly beautiful spot. Beyond the basin of water is an amphitheatre of shrubs and trees which is intersected by shady walks leading to a mount containing the grandest prospects of the Rhine and the Alps.

179. Public gardens or promenades are numerous and well arranged in France as in most countries on the continent: the demand for these arises from the social habits of the people and the mildness of the climate; and their growth, even in the middle of the cities, as in the Tuileries and Boulevards of Paris, and the street avenues of Bordeaux, Lyons, Marseilles, Montpellier, &c. is not impeded by the smoke of coal. What can be a greater luxury in a city than such a garden as that of the Tuileries situated in its centre,—its open scenes of gaiety and bustle, the distant hum of men heard in the stillness of its thick and shady groves, its lengthened perspectives of trees, vistas, statues, fountains, its coffee and refreshments, its music and dancing on certain occasions,—and finally, that sprinkling of mind thrown over the whole by the scattered stations of those who hire out chairs and periodical literature?

Subsect. 2. French Gardening, in respect to the Culture of Flowers and Plants of Ornament.

180. A taste for flowers was introduced to France from Holland, after that country had established commercial relations with the Levant and the south of Europe. (Deleuze, Recherches, &c.) Charlemagne loved gardens, and was most particular in giving directions to his gardeners. In his Capitulaire de Villis et Curtis, he enumerates the sorts of plants which he desires may be grown in all his gardens. This list, however, excepting the rose and the lily, is entirely medicinal; and these too, were probably used as drugs; for the greatest beauty, in barbarous times, is utility.

181. It was in the thirteenth century that ornamental plants began to be introduced to France as such. The crusades had brought to notice the gardens of the infidels in Egypt and Syria; the Christians invaders could not avoid being struck with their beauty, imitated their plans, and imported their productions into Europe.

182. The sixteenth century, however, had arrived before the culture of flowers was attempted. Botany now began to become a science, independent of medicine. Gardens were constructed, destined for curious and beautiful plants; and the discovery of America, and the passage to the Indies, augmented their number. Travellers collected seeds, which they sent home to their respective countries; great care was bestowed on such as appeared the most ornamental; of some flowers, double varieties were produced, and the colors and size of others, varied by culture, till advancing, by degrees, they at length became an object of luxury, and trade and caprice, fashion and variety, gave incredible prices for some of these productions; for in what, observes Deleuze, will extravagance not intermingle. Henry IV. had a taste for flowers: his gardener, Jean Robin, published a catalogue of plants in 1610, in which the passion flower and crown imperial are mentioned, the former as newly imported, and the latter as rare. In 1635, the varieties of tulips, ranunculuses, and anemones, in the Jardin des Plantes, exceeded that of the species in 1800. Evelyn mentions, in 1644, (Memoirs, I. 52.) a M. Morine, who from an ordinary gardener had become one of the most skilful persons in France, who had a rare collection of shells and flowers, and above 10,000 sorts of tulips alone. This florimania seems to have declined and given way to a taste for exotics, during the reigns of Louis the Fifteenth and Sixteenth, which has ever since continued to prevail.

183. The study of botany began to be cultivated in France at an early period, and has since attained great consideration in that country from the labors of Adanson, the two Jussieu's, Mirbel, Humboldt, and De Candolle. The first botanic garden was formed in 1597, at Montpelier in Henry the Fifth's reign, through the representations of Belon. In the following year it contained 1300 distinct species, the greater part gathered in the neighbourhood.

The garden of Paris (Jardin des Plantes) was founded by Louis the Thirteenth, in 1655, and finished in 1694, after, as La Brosse the first director remarks, 'eighteen years of prosecution, and six of culture.'
The subsequent history and description of this garden, at different epochs, are given by Adanson, Jussieu, and Thouin. It was visited by Sir J. E. Smith, in 1786, who observes that, "it used, in summer, to be the evening walk of literary people, and even of persons of fashion; and was, besides, frequented all day long by students, who, passing at close range, might be seen changing their descriptions; nor is it at all unusual, at Paris, for the fair sex to attend scientific lectures in considerable numbers. The collection of plants is generally reckoned inferior to that of Kew; it contains, however, many plants native to Ireland, mostly in the Levaux, and the Botanic gardens, and which improved since 1756, and now includes departments which may be considered, as far as vegetables are concerned, schools of horticulture, planting, agriculture, medicine, and general economy. It contains some fine old exotics, sugar-canes from which a loaf of sugar was made and presented to the Empress Josephine, a magnificent patrimony of gardens, and a hybrid for which the different volumes of the Annales du Musée, may be seen plans and descriptions of the garden, with the modes of instruction pursued by Professor Thouin. There can be no question of its being the most scientific and best kept garden in Europe, and an admirable hand in the last century in the opinion of the Chevalier Thouin, its director, and the professor of rural economy, has an equal claim to superiority as a scientific gardener.

The botanical garden of the Trianon, according to Deleuze, was established by Louis XV, at the suggestion of the Marquise de Voyer de la Côte. For the district of the king, there were one hundred and forty-six trees, and a general collection of plants, for the use of the garden of the royal family. Here B. de Jussieu disposed, for the first time, the plants in the order of natural families. The botanic department of this garden is at present in a state of neglect.

The Ashlar-garden of Aulnois in the time of Josephine was among the richest in Europe. Various botanical collectors were patronized, some jointly with Lee of Hammersmit. The seeds brought home by the navigator, Baudin, were here first raised and described by Ventenat in the Jardin de la Malmaison, in 1813. In 1815 Bonpland published the first volumes of the UL. rarum cultivées à Malmaison, which ruined him, and compelled him to seek an asylum in America. This garden, though comparatively neglected, contains some fine exotic trees as standards in the open ground, and protected in winter by moveable houses. Among these are Magnolia grandiflora and an orange-tree as large as they grow in Spain. In the hot-houses are many fine exotics, and the original bulb of that splendid plant, Brunsvigia superba, from the Cape of Good Hope. Towards the middle of the 18t, these provincial gardens have suffered from want of funds; and most of them are but indifferently kept up. We could not help being struck with this in viewing the very well contrived new garden at Marseilles, almost the only one of the richest provincial gardens for its size, and the best in order, after that of Paris, appeared to us (in 1819) to be that of Toulon. That of Rouen contains the original plant of the hybrid lilac (Syringa Rotha-magensis), named Varin, after the gardener who, about 1757, raised it from seed.

Herb or physic gardens are more common in France than in Britain. Plants form a much more important part of the Materia Medica of the hospitals and French physicians, than in this country, and their use is very ordinary among the lower orders. The herbarists of Paris occupy a particular lane, where they offer great variety of dried plants for sale.

Subsect. 3. French Gardening, in respect to its horticultural Productions.

184. The hardy fruits of France only exceed those of Britain by the olive, the fig, the jujube, pomegranate, and a few others little cultivated. Nature, Professor Thouin observes, (Essai sur l'Exposition, &c. de l'économie rurale, p. 55.) has only given to France, the acorn, the chestnut, the pear, the wild apple, and some other inferior fruits. Everything else which we have, agreeable or useful, is the product of foreign climates, and we owe them in great part to the Phoenicians, Greeks, Carthaginians, Romans and Saracens. The less ancient acquisitions are those of the crusades, or of accidental travellers. The vine, the peach, the fig, the mulberry, the cherry, and the olive, were doubtless introduced to France by the Romans; the orange by the Italians; and the pine-apple by the Dutch. Apples, pears, and plums, are the fruits recommended for cultivation by Charlemagne, in his Capit. de Villis et Curtis, &c. prepared about the end of the eighth century, and referred to by Montesquieu, as a chef-d'œuvre of prudence, good administration, and economy. The Abbé Schmidt informs us, (Mag. Encycl.) that this monarch, who had domains in every part of France, gave the greatest encouragement to the eradication of forests, and the substitution of orchards and vineyards. He was on terms of intimate friendship with the Saracenic prince, Haroun al Raschid, and by that means procured for France the best sorts of pulse, melons, peaches, figs, and other fruits. He desires that fennel, rosemary, sage, rue, wormwood, and above sixty other pot-herbs and medicinal plants, should be cultivated: one of these which he calls ancyllis (thought to be the house-leek) was to be planted before the gardener's house, probably as being vulnerary.

185. Early in the sixteenth century, it would appear they had at that time all the fruits now in use, excepting the pine-apple. (Olio. de Serres, and Steph. and Lieb.) Some remarks on the state of horticulture at the end of the century are given by Benard (Mém. de la Soc. Agr. du Seine et Oise, 1801.) and L. Deslongchamps. (Bon Jard. 1817-18.) Blaikie (169, 170.) informs us, that about 1779 only three sorts of melons were grown in France, the netted or Maraque, and two large sorts of poor flavor. Blaikie introduced the cantaloupe, which are now the prevailing sorts. The pine-apple has never been successfully cultivated in France, it becomes sickly from exhalation, and produces small fruit as in Italy. (99.) But France excels all other countries in pears and plums, and produces excellent peaches.

186. The ordinary vegetables of France have not been increased from the earliest
period of horticultural history, with the exception of the sea-cale and the potatoe. In salading and legumes they far excel most countries; but in the cabbage tribe, turnips, and potatoes, they are inferior to the moister climates of Holland and Britain.

187. A sort of forcing seems to have commenced in France towards the end of the sixteenth century. Béarnard informs us, that arcades open to the south were first erected in Henry IVth's time, for accelerating the growth of pease at St. Germainens en Laye; and that, in the end of the reign of Louis XIV., Fagon, at the Jardin des Plantes, constructed some hot-houses with glass roofs, which he warmed with stoves and furnaces for the preservation of tender plants; and which gave rise to all the hand-glasses, frames, and hot-houses subsequently erected in France. Melons and early cucumbers had been hitherto grown on beds of dung, and covered at night with loose straw; early salading was raised in pots and boxes exposed to the sun during day, and placed in sheds or arbors during night. But Richard Senior, observing what Fagon had done, built for himself at St. Germainens, and afterwards for Louis XV. at Trianon, hot-houses, in which were seen, for the first time in France, peaches, cherries, plums, strawberries, bearing fruit in the depth of winter. In the Ecole Potagère, written by Combes about the year 1750, are the details relative to these buildings. There is still, however, very little forcing in France, and almost none in the market-gardens. Pease, potatoes, asparagus, kidney-beans, salads, &c., are seldom or never forwarded by other means than by planting in warm situations under south walls, and grapes or peaches are never covered with glass. Melons and seedling plants of different sorts are forwarded by beds of dung, generally without the addition of sashes and frames.

188. French horticulture received a grand accession of theoretical and practical knowledge from the writings of Quintinye. Jean de Quintinye was born at Poitiers in 1626, put to school among the Jesuits, took lessons in law, and afterwards travelled to Italy with Tambonneau. Here his taste for agriculture began, or greatly increased. He applied to its study as a science, and, on his return, Tambonneau committed his gardens to his care. He attracted the attention of the court soon afterwards, and was made director of several of the royal gardens during the reign of Louis XIV. He laid out a jardin potager of thirty acres at Versailles; the inhabitants of which, Neill observes, seem to have imbibed from him a taste for horticulture and botany, the "Confrères de St. Fiacre," (the tutelar saint of horticulturists,) or gardener's lodge, held here, being the oldest in France. (Hort. Tour, 414.) Among other works, Quintinye wrote The complete Gardener, translated by Evelyn, and abridged by London and Wise. He died in 1701. After his death the king always spoke of him with regret, and Switzer says, assured his widow, that the king and she were equally sufferers. Quintinye, in his work on fruit-trees, has developed a system of pruning, which has not yet been surpassed by that of any other author. Before his time the culture of wall, or espalier trees, was little attended to; gardens had been generally surrounded by high hedges, but for these were now substituted walls of masonry, or of earth en pisé. The pruning of peach and pear trees is now well understood in France, and horticulture on the whole is making rapid advances.

Subsec. 4. French Gardening, in respect to the planting of Timber-trees and Hedges.

189. Planting for profit has never been extensively practised in France, owing to the abundance of natural forests in every part of the kingdom. These forests were much neglected till within the last thirty years; but they are now (being mostly national property) under a more regular course of management; their limits defined by fences, and the blanks filled up from the national nurseries. The roads of France being also kept up by government, much attention is paid to lining them with rows of trees. In some places, as in Alsata, the walnut, cherry, apple, pear, and other fruit-trees are used; in other districts the elm, oak, or poplar, are employed; and in the south, we frequently find the mulberry, and sometimes the olive. The resinous tribe are rarely planted but for ornament; the oak, elm, beech, and Spanish chestnut, are the chief sorts used to fill up blanks in the natural forests.

190. The idea of cultivating and naturalising foreign trees in France was first projected by Du Hamel in the time of Louis XV. He procured many seeds from America, raised them in the royal nurseries, and distributed them among his friends. A vast plantation of exotic trees was then made at St. Germainens en Laye by the Mareschal de Noailles. Lamoignon naturalised on his estate at Malsherbes a great number of these trees, and at the age of eighty-four, Deleuze observes, saw every where in France plants of his own introduction.

191. Hedges are not in general use in France; the plants employed in field-hedges, in the northern parts, are the hawthorn, birch, or a mixture of native shrubs, as hazel, briar, laburnum, &c. In Languedoc the most common plant is the wild pomegranate. In ornamental hedges they have attained great perfection; for these the
favorite plants are the yew, the hornbeam, and the box; and for tall hedges, the lime and elm.

Subsect. 5. French Gardening, as empirically practised.

192. The use of gardens is very general in France. Few cottagers are without them, and in the northern districts, they commonly display a considerable degree of neatness, and some fruit-trees and flowers. The southern parts of the country are the least civilized; there the gardens of the laboring class are less attended to, and gourds or melons, and Indian corn, as in Italy, are the chief articles grown. The gardens of the ordinary citizens and private gentlemen in France, are greatly inferior to those of the same class in Holland or Britain; they are seldom walled round, and rarely contain any arrangements for foreign or tender exotics. A green-house, indeed, is a rare sight, and there does not seem to exist the slightest desire for enjoying any vegetable production either earlier or later than their natural seasons. There are few wealthy men in France at present, and consequently few first-rate gardens; the best are in the northern districts, and belong to princes of the blood, bankers, and other opulent citizens. Those of the Dukes of Orleans and Bourbon, of Perigord, Laffite, and De laborde, may be included in this class; though they are far inferior to many citizens’ seats and gardens in England.

193. There are excellent market-gardens in the neighbourhood of Paris, where, by force of manure and daily waterings, the oleraceous tribe are brought to a large size and very succulent quality. Figs, for the market, are grown by a particular class of fruit-growers at Argenteuil; grapes at Fontainbleau, peaches at Montreuil, and cherries at various villages to the east of the city. There are numerous florists who devote themselves exclusively to the culture of flowers, and supply the market with roses, lilies, stocks, and the more common greenhouse plants and orange-trees. The latter are very neatly grafted, and otherwise well managed. In the winter time forced flowers are exposed for sale, and also summer flowers which have been dried in stoves, and preserve their color perfectly. The same thing is done with aromatic herbs, and some pot-herbs, as parsley, chervil, &c.

194. There are few nurseries in France; the best are at Paris, and are chiefly occupied with the culture of fruit-trees and ornamental shrubs. They excel in the culture of the rose, of which they have upwards of 300 sorts, which form, to a small extent, articles of foreign commerce. The two best provincial nurseries are those of Audibert at Tonelle, in Languedoc, and Sedi at Lyons. Valley’s at Rouen is celebrated for orange-trees, and Calvert and Co.’s (Englishmen) at Bonne Nouvelle, near the same place, equally so for roses; Vilmorin is the agricultural seedsmen, Noisette the Lee, and Cels of Mont Rouge the Lodidge of Paris. France long supplied a great part of Europe with fruit-trees, from the celebrated nursery of the fathers of the Chartreux, near the Luxembourg, established in the time of Louis XIV, and including eighty acres. That establishment does not now exist; but Ville Hervé, the son of its former manager, has the care of the collection of fruit-trees and vines in the national garden of the Luxembourg. The extensive collection of grapes in this garden was formed by Chaptal, the celebrated chemist, when minister of the interior, with a view to ascertain the best sorts, and distribute them in the provinces, and the fruit-trees were brought by the elder Hervé from the Chartreux. (Preface to the Catalogue of the Luxembourg Garden, 1814; Cours d’Agriculture, &c. art. Vigne.) When Blaikie went to France in 1776, there was not a nursery for trees and shrubs in the kingdom. About Vitry only a few of such forest-trees were cultivated as were used in avenues, and so few fruit-trees that the sorts were not tailed; the cultivators like the orange nurserymen at Nervi (95) recognising the few sorts by the leaves and bark.

195. The operative gardeners in France are, in general, very ignorant. Few of them have learned their art by regular application, or the customary engagement of apprenticeship. At Paris they are poorly paid, and work much harder than the same class in England. Evelyn, in 1644, informs us, that the work of the royal gardens was all done in the night-time, and finished by six or seven in the morning, in order, no doubt, that nothing offensive might meet the eyes of the great of these times. Happily such a clasm does not now exist between the rich and the poor; but still, partly for the same reason, but principally to avoid the mid-day sun, the great part of the work, in most private gardens, is performed from three to nine o’clock in the morning, and again from six to nine in the evening. The great recommendation of a French gardener is, to be able to construct a garden a bon marché; and the greatest to prune trees a la Montreuil.

196. Of artists in gardening (artistes jardiniers, architectes des jardins,) there are a number in France, chiefly resident in Paris. Blaikie, already mentioned, and Gab. Thiouin, brother to the professor, and author of Plans Raisonnés des Jardins, &c. (1818) may be reckoned the most eminent. Girardin, Morel, and De Lalle may be considered as hav-
ing established the principles of gardening in France, as an art of design and taste; but it does not appear clear that the artists in general have caught their principles.

**Subsect. 6. French Gardening, as a Science, and as to the Authors it has produced.**

197. The science of gardening is well understood in France among the eminent gardeners and professors; perhaps better than in any other country. Quintinye and Du Hamel applied all the physiological knowledge of their day to the treatment of fruit and forest trees; and the theory of grafting, of healing wounds, and of artificial excitements to fruitfulness, was explained in their works. Buffon, Magnal, Parent, and Rosier, Aubert de Petit Thouars, Bosc, and above all Professor Thouin, have brought the whole science of chemistry and of botany to bear on the various parts of gardening and rural economy, which they have treated in various works, but especially in the *Nouveau Cours d'Agriculture*, (14 vols. Svo.) published in 1810.

198. The court and national gardeners have, for the last thirty years, been men eminent for scientific and practical knowledge; who have received a regular education, and rank with other crown officers. It is not there as in England, where the royal situations have always been occupied by more empirical practitioners, recommended by some court favorite, or succeeding by the common chances of life.

199. The great mass of operative gardeners in France, both as masters and labourers, are incomparably more ignorant both of gardening, as a science, and of knowledge in general, than the gardeners of this country; few of them can read; and the reason of this ignorance is, that there is no demand for good master-gardeners. The pupils and apprentices of the *Jardin des Plantes* are mostly sent to manage the provincial botanic gardens, or to the few proprietors who have first-rate gardens. The chief of them are foreigners, who return to Germany or Italy. Indeed, where there is no forcing, and few plants in pots, scientific gardeners are less necessary; the management of fruit-trees in France being reduced to mere routine.

200. The French authors on gardening are very numerous, but Quintinye is their most original and meritorious writer on horticulture, Du Hamel on planting, and Girardin and D'Argenville on landscape-gardening. Their works on flowers are chiefly translations from the Dutch.

**Sect. IV. Of the Rise, Progress, and present State of Gardening in Germany.**

201. The Germanic consideration, as arranged in 1815, includes the empire of Austria, the kingdoms of Prussia, Bavaria, Saxony, Hanover, Wurtemburg, and Denmark, besides various dukedoms and free towns. The materials which we have been able to collect for so extensive a field, are exceedingly scanty; and, indeed, it appears from Hirschfield, that gardening made little progress in Germany till the seventeenth century. At present, the taste for our art there is very considerable, and seems to have received a new stimulus from the recent peace. "Gardens," Madame de Stuël observes, "are almost as beautiful in some parts of Germany as in England; the luxury of gardens always implies a love of the country. In England, simple mansions are often built in the middle of the most magnificent parks; the proprietor neglects his dwelling to attend to the ornaments of nature. This magnificence and simplicity united do not, it is true, exist in the same degree in Germany; yet in spite of the want of wealth, and the pride of feudal dignity, there is everywhere where to be remarked a certain love of the beautiful, which sooner or later must be followed by taste and elegance, of which it is the only real source. Often, in the midst of the superb gardens of the German princes, are placed Selenian harps, close by grottoes, encircled with flowers, that the wind may waft the sound and the perfume together. The imagination of the northern people thus endeavours to create for itself a sort of Italy; and during the brilliant days of a short-lived summer, it sometimes attains the deception it seeks." (Germany, chap. i.)

**Subsect. 1. German Gardening, as an Art of Design and Taste.**

202. The French style of gardening has prevailed in Germany from the earliest period of history or tradition. The German architects, observes Hirschfield in 1777, in making themselves masters of the gardens, as well as of the houses, tended to spread and perpetuate the prejudice. "A singular and deplorable Gallican persuades Germany from the prince to the peasant, which neither irony, patriotism, nor productions which show the force of our natural genius could destroy; 'ainsi font les Français; voilà ce que j'ai vu en France;' these words were sufficient to reduce the German to a mere copyist, and in consequence we had French gardens, as we had Parisian fashions. Our nobles gave the first example of imitation, and executed on their estates little miniatures of Versailles, Marly, and Trianon. But now (1777)," he adds, "the Aurora of judgment and good taste begins to arise in our country, and the recitals of the happy changes made in England in the gardens, has prepared the way for the same revolution in Germany. However, we
cannot complain of the suddenness of that revolution, and that the imitation of the English taste spreads too rapidly; it appears, on the contrary, that we begin to think for ourselves, and reflection proceeds much slower than mere imitation. We may meet perhaps here and there several copies of the British manner, perhaps even of the Chinese style; but we expect to see the Germans inventing and combining for themselves, and producing gardens stamped with the impression of national genius.” (Théorie des Jardins, tom. i. 83.)

204. The climate and circumstances of Germany are less favorable to landscape-gardening than Britain. Meyer, a scientific practical gardener and author, who studied his art in the royal gardens at Paris, and afterwards spent some time in England, viewing the principal country-seats, is of this opinion. (Pom. Franc. 1776.) He considers grounds laid out in the ancient style, as "insipid and monotonous, from their regularity, and only calculated to produce sadness and ennui. If their aspect strikes at the first glance, it fatigues and tires at the second, and certainly is revolting and disgusting at the third." He admires English gardens in England, but states three objections to their introduction in Germany. The inferiority of the pasturage, the expense and want of space, and the necessity and advantage of attending to the culture of legumes and fruits. A mixed style is what he prefers, and what he adopted in the episcopal gardens which he laid out and managed at Wurzburg.

205. Austria. Francis the First, about the middle of the seventeenth century, laid out or greatly enlarged the gardens of Schoenbrunn, after the plans of Steckhoven, a Dutch artist. These gardens occupy a plain and a long ridge or hill near the capital, and are much admired for their extent and simple, though formal grandure. They are inferior to those of Peterhoff and Versailles in respect to fountains, and to those of Sans Souci and Lodoquisi for statues and antiques; but for simple massive grandure, for shade and verdure, and all the more simple beauties of the ancient style, they are, we believe, superior to any gardens now existing in Europe.

The Augarten (eye-garden, or garden of pleasure) is a public promenade in the suburbs of Vienna. It is a circular space of ten acres, surrounded by an elevated broad terrace-walk, commanding extensive views; and the area is planted and subdivided by walks. At the entrance is a magnificent coffee-house. It was formed during the reign of the benevolent emperor Joseph, whose particular wish it was, that it should be open to every class of citizens.

The Prater, or meadow, is an extensive public promenade of a different description, and suited both for promenades en cheval and au pied. It forms part of an island in the Danube, and consists of an artificial grove used as a tea-garden; an avenue as a course for carriages, but chiefly the scattered remains of an ancient forest of oaks and thorns used for walking, and for exhibiting all manner of fêtes. We consider it the most agreeable scene of the kind on the continent. Here, in the summer evenings, all Vienna is assembled; the imperial family mix familiarly with the people, and Francis the Third, unattended, and in the plainest garb, selects his table and rush-bottomed chair, and calls for his coffee and segar, like any other citizen. Economical in his administration, frugal in his personal expenses, and exemplary in his morals, he has nothing to fear from a personal familiarity with his subjects. Both the Prater and the garden were planted with full-grown trees; for Joseph II. as Pezzel, his biographer, informs us, wished to see the effect of all his improvements.

The imperial gardens of Luxemburg are extensive, avowedly English, and display a good deal of our manner; but more, as we have elsewhere observed (Ed. Encyc. art. Landscape G.), in the taste of Brown than of Kent.

206. In Hungary, Hirschfeld, in 1783, says there are only the gardens of Esterhazy, a seat of Prince Esterhazy, worthy of notice, and that they were chiefly indebted to the beauty of the palace for their attractions. Dr. Townsend, in 1798, mentions Count Vetzey as laying out his grounds in the English style, aided by a gardener who had been some time in England. The gardens of Count Esterhazy of Galantha, at Dotis, he considers very fine; and those of the Bishop of Esllau, at Félcho-Tarkan, as romantic. Dr. Bright (Travels, 1815) mentions Kórmond, the property of Prince Balhyani, as containing a very handsome garden in the French taste, with considerable hot-houses and conservatories.” Graaf Brunswick of Marton Vassar, had passed some time in England, and his garden was laid out in the English style. The favorite mansion of Prince
GARDENING IN GERMANY.

Esterhazy is Eisenstadt; the palace has lately been improved, and the gardens, which were laid out in 1754 in the French taste, were, in 1814, transforming in the English manner. (Travels in Hungary, 346.)

207. At Dresden, the royal and principal private gardens exhibit nothing remarkable in the way of art. They were formed chiefly during the electorate of Frederick Augustus, King of Poland, and are remarkably confined, and by no means interesting in detail. The situation and environs of Dresden every one feels to be delightful; but there is perhaps no city of the same rank on the continent equally deficient both in ancient and modern gardens. (Ed. Encyc. art. Landscape Gard.)

208. Prussia. Almost all the geometric gardens of Prussia were formed during the propitious reign of Frederick II.

The Thiergarten at Berlin is the most extensive. It is a sort of public park or promenade, on a flat surface, and loose arenaceous soil, intersected by avenues and alleys, pierced by stars and pales d'oeil, varied byobelisks and statues, and accommodated with public coffee-houses, sheds for music and rural fêtes, and open areas for exercising troops. The ancient gardens of Sans Souci at Potsdam are in the mixed style of Switzer, with every appendsapp and ornament and ornament of the French, Italian, and Dutch taste. Various artists, but chiefly Manger, a German architect, and Salzmann, the royal gardener, (each of whom has published a voluminous description of his works there,) were employed in their design and execution; and a detailed topographical history of the whole, accompanied by plans, elevations, and views, has been published by the late celebrated Nicholai of Berlin, at once an author, printer, bookbinder, and bookseller. The gardens consist of, 1. The hill, on the summit of which Sans Souci is placed. The slope in front of this palace is laid out in six terraces, each ten feet high, and its supporting wall covered with glass, for peaches and vines. 2. A hill to the east, devoted to hot-houses, culinary vegetables, and slopes or terraces for fruit-trees. 3. A plain at the bottom of the slope, laid out in Switzer's manner, leading to the new palace; and 4. A reserve of hot-houses, and chiefly large orangeries, and pits for pines to the west, and near the celebrated windmill, of which Frederick could not get possession.

The Sans Souci scenery is more curious and varied, than simple and grand. The hill of glazed terraces crowned by Sans Souci has indeed a singular appearance; but the woods, cabinets, and innumerable statues in the grounds below, are on too small a scale for the effect intended to be produced; and on the whole distract and divide the attention on the first view. Potsdam, with its environs, forms a crowded scene of architectural and gardening efforts; a sort of royal magazine, in which an immense number of expensive articles, pillared scenery, screens of columns, empty palaces, churches, and public buildings, as Eustace and Wilson observe, crowd on our eyes, and distract our attention. Hirschfeld, who does not appear to have been a great admirer of Frederick, and who, as the Prince de Ligne has remarked, was touched with the Anglomania in gardening, says, in 1775, "according to the last news from Prussia, the taste for gardens is not yet perfect in that country. A recent author vaunts a palace champêtre, which presents as many windows as there are days in the year: he praises the high hedges, mountains of periwinkle, regular parterres of flowers, ponds, artificial groetttes, jets d'eau, and designs traced on a plain." (Théorie, &c. tom. v.393.)

209. The principal examples of the English style in Prussia are the royal gardens at the summer residence of Charlottenburg, near Berlin, begun by Frederick the Great, but chiefly laid out during the reign of Frederick William II. They are not extensive, and are situated on a dull sandy flat, washed by the Spree; under which unfavorable circumstances, it would be wonderful if they were very attractive. In one part of these gardens, a Doric mausoleum of great beauty contains the ashes of the much-lamented queen. A dark avenue of Scotch firs leads to a circle of the same tree, 150 feet in diameter. Interior circles are formed of cypresses and weeping-willows; and within these, is a border of white roses and white lilies (Lilium candidum). The form of the mausoleum is oblong, and its end projects from this interior circle, directly opposite the covered avenue. A few steps descend from the entrance to a platform, in which, on a sarcophagus, is a reclining figure of the queen: a stair at one side leads to the door of a vault containing her remains.

210. The garden of the palace of the Heiligense (fig. 15.) is avowedly English, and is in much better taste than that at Charlottenburg. The palace is cased externally with
HISTORY and or, but and, but and, or, these our left the the lead tain considered a tent work, than continually the gardens of Marienlust, near Elsinour, which occupy the same space as those in which Hamlet's father was murdered, and those of the Prince Frederick, near the city, may be considered the Greenwich and Hyde Parks of Copenhagen. Hirschfield mentions Asberg, on the lake Pleon, as one of the finest residences in Denmark in his time, and enumerates nearly a dozen others as seats of great beauty.

Dronningard may be considered as one of the best examples of the English style. It is an extensive park, the late residence of an eminent Danish banker, De Coninck, about sixteen miles from Copenhagen. The grounds are situated on a declivity, which descends to a natural lake of great extent, whose circumjacent shores are verged with rich woody scenery, and country-houses. The soil here approaches more to a clayey loam than is general on the continent; and the climate being cold, the turf is happily of a deep tone of green, and close texture. The oak and beech abound in these grounds, as well as firs, and a number of exotic. Buildings are not too frequent; but there are several, and among them is the residence of the count. One of the family actually retired, on occasion of a matrimonial disappointment, and lived there for several years, till roused and restored to active life by the dangers of his country. There are numbers of small spots of cultivation, or country seats, in which something of the English style has been imitated; but in none of the gardens of the court has it been avowedly introduced.

There are many celebrated gardens in so extensive a country as Germany, that we cannot find room to particularise. The royal gardens of Munich, Stuttgart, and Hanover, the gardens of Baden, Hesse Cassel, Hesse Darmstadt, Saxe Gotha, Weimar, Worlitz, Schweitzingen, and other places, are well deserving notice. Most of them will be found described in Hirschfield's work, or noticed in the Lettres et Pensions of the Prince de Ligne; and the most modern are described in the Almanach du Jardinage, a periodical work, published at Leipsic; or, in the Gardener's Magazine, a quarterly periodical work in the German language. Indeed, there are specimens of English gardening, more or less extensive, in or near the capital towns of every state in Germany; but, by far the greater number are of a very inferior description. From the arid soil and limited extent result bad turf and an air of constraint; and from too many buildings and walks, a distracting bustle and confusion. They are crowded with windind sanded paths continually intersecting each other, little clumps, and useless seats or temples, and very frequently resemble more the attempts of mimics or caricaturists, than imitators of our taste. On the continent, indeed, the defects of the English style are more frequently copied than the beauties; which, we presume, arises from the circumstances of few of those who lay out such gardens, having had a proper idea of the end in view in forming them, viz. a painter-like effect in every case, where it does not interfere with utility, or some other preferable beauty; and, in many cases, an entire allusion to natural scenery. It is difficult for a person of limited education and travel to form a distinct idea of what English gardens really are. The foreigner can seldom divest himself of the idea of a very limited and compact space as requisite for this purpose; the reverse of which is the case with all our best scenes of picturesque beauty. The English gardens in the vicinity of Dresden, Brunswick, Hamburgh, Prague, Toplitz, Leipsic, and other places, have given rise to those remarks, in which even those professedly English in Prussia might be included. There are some exceptions which might be pointed out at Cassel, Stuttgart, (for views of these gardens, see l'Almanach du Jardinage,) Weimar, not unlike Kensington gardens, (see Description du Parc de Weimar, et du Jardin de Tieffurth, Erfurt, 1797,) the park of Fürstenburg near Breslaw, Merpentheim, Worlitz, praised by the Prince de Ligne, and the walk at Munich, laid out by Count Rumford. (Ed. Encyc. art. Landscape Gard.)

The Duke of Baden's gardens at Schweitzingen (fig. 16), between the Rhine and the Mayne, are considered by Kraft as the most delightful in Germany. They cover a surface of about 300 acres, and contain the ancient castle of the Marqueses of Baden. (1.) "The marquisate of Baden," says Kraft, "having progressively and considerably increased by means of a numerous family, wings were obliged to be built on each side, dividing the houses, which formerly (figs. 2, 5) had been much increased. In front and more advanced, is the garden, in the French style, executed on a circular plan. In the middle of the avenue are four grass plots, bordered and enamelled with flowers. In the middle are little basins with fountains, one of which (5) throws the water sixty-seven feet high. On the right and left are plantations of odoriferous shrubs, orange trees, statues, and vases of the finest marble. Farther on are discovered the gardens, called the gardens, situated on the right and left, laid out in different forms, and embellished with a number of figures, vases, statues, the temple of Minerva (4), the temple of Venus (6), and Vesta (7). Higher up is the garden of the large grove, ornamented with numerous figures, (7, 7, 7, 7), altars, tombs, urns, etc. Shady walks lead to the great basin (8), the gates leading to which have groups of figures on the pedestals (9, 9). The Grand Duke reserves the grand basin for the amusement of his family, par des petites navigations. A very magnificent Turkish mosque (10) is erected on the left. Here begins the picturesque garden, with artificial hills, vales, and slopes; many different sorts of trees; a temple of Mercury in ruins (11); and va-
GARDENING IN GERMANY.

Gardening is a serious business in Germany, and the German gardener is particularly anxious to have his walks, leading through shrubberies to the right, till you arrive at the nursery-garden (12). From thence, crossing the canal, you arrive at the temple of Apollo (15), built of costly marble. In the garden behind, are rocks with allegorical figures, subterraneous caves and caverns; at one side a family bath of marble (14), aviaries (15), cabinets, pleasure-garden, and basin for aquatic fowls (16 & 17); small buildings, in the form of monuments (18), serving as cabinets of natural history, museums, a laboratory, &c.; a picturesque garden and temple (19); a Roman aqueduct (20), supplied by a water-engine (21), a ruined aqueduct (22); the offices for the administration of the garden, with its appurtenances (23); a large theatre (24); residence of the director-general (25); of the inspectors of the garden (26); of the inspectors of the forest (27); of the huntsmen (28); of the foresters (29). Besides all these things and many more, there is a fruit-garden (30); kitchen-garden (31); private orangery (32); area for greenhouse plants in summer (33); and lofty water-engine for conveying water to the castle (34).

The Ducal gardens of Saxegotha are remarkable for their fine lawns, and for a ruined castle, which was first built complete, and then ruined express, by firing cannon against it.

SUBSECT. 2. German Gardening, in respect to the Culture of Flowers and Plants of Ornament.

215. Floriculture was but little attended to in Germany, previously to the introduction of botanic gardens; but on the establishment of these, plants of ornament were eagerly sought after in most of them: that of Altorf was famous for orange-trees, and that of Copenhagen for bulbous roots.

216. The earliest private botanic garden in Europe, next to those of Italy, is said (Keith's Botany, p. 18.) to have been one formed by William, Landgrave of Hesse, early in the sixteenth century. Since that period more private botanic gardens have been formed in Germany than in any other continental country. At Carlsrouhe, the Prince of Baden Dourlach formed a botanic garden in 1715, in which, in 1737, there were 154 varieties of oranges and lemons. Many might be named from that period to the present: the latest is that of the Prince of Salm-Dyck. It was laid out in 1820, by Blaikie, of St. Germain; and is calculated to contain all the hardy plants which can be procured, arranged in groups, according to the Jussieuian system. The prince is advantageously known, by his works on succulent plants.

217. The first public botanic garden in Germany, according to Deleuze (Annales du Musée, tom. 8.), was established by the Elector of Saxony, at Leipzig, in 1580; this magistrate having undertaken the reform of public instruction throughout his dominions.

Those of Giessen, Altorf, Rintel, Ratibon, Ulm, and Jenna, soon followed. In 1605, Jungerman, a celebrated botanist, obtained one for the university, which the landgrave had just founded at Giessen. After having disposed of it, he went to Altorf, and solicited the same favor for this city. The senate of Nuremberg agreed to his wishes in 1620, although the country was then a prey to the disasters of war. Jungerman,
named Professor, gloried in the prosperity of a university which he looked upon as his work, and in 1635, he published the catalogue of the plants he had collected. Ten years afterwards they constructed a glass-house, and the garden of Altorf (Prof. to the Nuremberg Hospites) was then the most beautiful of Germania, and which Erxleben, Count of Shawenburgh, established in 1621, at Rintel, in Westphalia, also acquired much celebrity. These plant enthusiasts, in an arc of the same University of Jena was founded, the professors of botany, during the summer season, took the students to the country to herbalise. They soon found it would be much more advantageous to collect in one place the plants wished to be acquainted with, and the government constructed a garden in 1629. The direction of it was given to Rolfine, who has left a curious work on plants, containing a history of the principal gardens of Europe of his time.

21. Lepis. Towards the end of the seventeenth century, the garden of Gaspard Boe was celebrated. He introduced many plants, among them the dwarf almond.

22. At Vienna and Frankfort, L'Ecluse prosecuted the study of botany, and enriched the gardens at these places with an immense number of plants. Maximilian II., who occupied the imperial throne from 1564 to 1576, had a magnificent garden to be constructed at Vienna for the plants which he collected, charging his ambassadors at Constantinople and other countries, to bring home plants; and giving the care of the garden to L'Ecluse. Rudolph I., who succeeded Maximilian, also enriched his garden, of which Sweet published a catalogue (Florilegium) in 1612.

The gardens of the princes are of two kinds, in with the palace, in 1743, by the Emperor Francis I. He declared that that establishment should be worthy of the imperial magnificence, and that it should extend the domain of botany, in bringing together vegetables then unknown in Europe. By the advice of Van Swieten, he procured two celebrated florists, the one from Leyden and the other from Delft. The first, Adrian Steckhoven, directed the construction of the hot-houses; and the second Van der Sacht, brought the all the plants which he could collect in the gardens and nurseries of Holland. Thus the first year they were in possession of many curious species; but this was only a step towards the end they had in view. The Emperor proposed to the collected the Jaccquin to go to the Antilles. This botanist departed in 1754, accompanied by Van der Schacht, and two Italian zoologists, employed to procure animals for the menagerie and the museum. These travellers visited Martinique, Grenada, St. Vincent, St. Eustace, St. Christopher, Jamaica, and other islands. In 1755 they sent off their first packages, and in 1756, Van der Schacht arrived with a collection of trees and shrubs almost all in flower condition. The trees were six or six feet high, and many had already borne fruit; they were taken up with balls, and the earth enveloped with leaves of bananas, tied by cords of Hibiscus tiliaceus. Thus packed, one with another, they weighed 100,000 pounds, and the Emperor ordered to water these plants, and be transported to the country of a vessel which had been forwarded from Martinique for Leghorn. From Leghorn the plants were transported on the backs of mules, and placed in the plain ground in the hot-houses built to receive them. The third quantity of the four hundredth plants came to the same height; and there are three more ranges, each about 240 feet long.

An accident in 1750 caused the loss of most of the plants of the great hot-house. Van der Schacht being sick, the person who supplied his place, forgot, during a very cold night, to light the stove. Perceiving it in the morning, he thought to remove the evil making a very large fire in the chimney of the hot-house; but the flames perished many of the trees to perish, whose trunks were of the thickness of the arm. To repair this loss, Joseph II. engaged the naturalists to undertake a new voyage. Professor Mäser was named chief of the expedition, with Dr. Stupiez, for a companion; the gardeners Boe and Brederemy, and the draftsman Mol. They went direct to Philadelphia, visited the United States, Florida, and New Providence, sent home a large collection, and Boe afterwards got charge of the garden of Schoenbrunn.

The hot-houses of Schoenbrunn, Townsend owns (Voyage in Hungary), are the most spacious that have yet been constructed in Europe; the trees of the tropics there develop their branches in full liberty, and bear flowers abundantly. The most rare, the Cocos nucifera, the Cargota venus, the Elaiss guineensis, grow there with vigor. The Corpia umbraculifera extends its large leaves for twelve feet round, and birds of Africa and America there fly from branch to branch among the trees of the country. Jacquin published successively three great works, illustrating the plants of these gardens, viz. Hortus Schoen., Icones plant, rariorum, and Fragmenta Botanica. We found these gardens in 1814 in suitable order; but the edifices requiring renovation. It is difficult for a mere European traveler to form any idea of the grandeur of the palms sending out their immense leaves from the capitals of their column-like trunks.

There are at Vienna two public botanic gardens; the one formed in what was a large gravel-pit extent of land, and the other of smaller extent, attached to the university, and devoted to a small general collection. Considerable compartments in the gardens of Leichtenstein, and Schwartzberg, in Leopoldstadt, are devoted to the culture of ornamental plants systematically arranged.

The botanic garden of Pesth was established in 1812, and enlarged in 1815; it was placed under the direction of the professor Kitaibel, known in the scientific world as the author of Plantae rariorum Hungariae.

219. The botanic garden of Dresden is small; but is rich in exotics lately procured from England, and carefully managed by Traugott Seidel.

The botanic garden of Berlin was established in the time of Frederick I. in 1700, in which the arrangement of the plants is according to their native habitations. It has lately been greatly enlarged under Link and Otto, and consists of Mathiast, Stuttgard, Baden, Hesse, and most others in Germany, by their respective directors and gardeners.

The botanic garden of Königsberg, was enlarged and re-arranged in 1812, and deserves notice for its uncommon size, and number of plants, according to Professor. It was established before 1690. It was rich in hardy plants and trees, to the end of the last century, but is at present rather neglected. Sperlin in 1694, and Pauli in 1655, published catalogues of this garden.

220. The taste for plants in Germany is very considerable among the higher classes; and not only public bodies but private gentlemen, and princes of every degree, spend a much greater proportion of their income, in the encouragement of this branch of gardening, than is done by the wealthy of England. Since the restoration of tranquility, this taste has received a new stimulus by the opportunity afforded of procuring plants from other countries. Among the lower classes, however, a taste for flowers is less popular in Germany than in Italy, Holland, and France; probably owing to their frugal habits, and comparatively sober enjoyments.
In Austria the best varieties of hardy fruit-trees are said (Bright's Travels) to have been introduced from Holland, by Van der Schot, about the middle of the seventeenth century; but many of them must have been in the imperial gardens long before this period, from the connection of Austria with the Netherlands; yet Meyer, in 1776, speaking of fruits, says, that "the age of Schoenbrunn will be for Franconia what that of Louis the Fourteenth was for France." The Rev. J. V. Sickler, in Saxegotha, Counsellor Diel, at Nassau Dietz, and Convent at Raciborin, before he was established, within the last fifty years, fruit-tree nurseries, where all the best Dutch, French, and English varieties may be purchased. Diel and Ranslesben prove the sorts, by fruiting the original specimens in pots in a green-house. Sickler has fruited an impermeable pear, the fruit of which was round, and the surface, and published descriptions of them in Der Teutsche Obst. Gartner; a work of which 48 volumes have already appeared.

In Hanover George II., after establishing an agricultural society, is said to have introduced the best English fruits about 1731. At the Earl ofarend, in the neighbourhood of Dresden, said to be the most northerly in Germany. He introduced fliced walls, and trained the best sorts of English peaches and apricots on them. The whole of his horticultural efforts and his chateau were destroyed by the French army in 1813, for no other reason than his being an Englishman. A public walk and seat at Carlsbad remain to commemorate his taste and public spirit.

At Potsdam the best fruit-trees were introduced by Frederick II., who was passionately fond of them, and cultivated all the best Dutch varieties on walls, espaliers, under glass, and in the open garden. He was particularly fond of pine-apples, of which he grew a great number in pits; and is censured by an English traveller (Burnett), because, on his death-bed, he made enquires after the ripening of one of them, of which he expected to make a last bonne bouche. Potsdam and Schwobber are the only parts of Germany where for many years has been practised to any extent. There are now in the royal gardens of Prussia, excellent fruit trees in the care of the director Linne, who has visited England.

At Weimar, the chief proprietor of the Landes industrie comitit, and author of a work on potatoes, is said to have introduced the finest garden and extensive hot-houses where he raises the finest fruits. The whole, Jacobs observes (Travels, 1819, 232), is kept in order.

In Hungary horticulture has been much neglected, but fruit-tree nurseries were established there by government in 1808, and private gentlemen. Plums, Dr. Bright informs us, are cultivated in order to make damson brandy. The Tokay wine is made from the variety of grape figured and described by Sickler, in his Garden Magazine of 1814, as the Hungarian blue. The soil of the Tokay vineyards is a red brown clay, mixed with sand, incumbent on a clayey slate rock; and it is observed by a Hungarian writer quoted by Dr. Bright, that "in proportion as is soil poor and stony, and the vine feels the effects of the climate and situation, becomes more excellent in quality." Tokay wine is made in the submontane district which extends over a more than twenty miles round the town of that name. The grapes are left on the plants till they become dry and sweet, they are then gathered and put in a cask with a perforated bottom, and allowed to remain till that portion of the juice escapes which is called Tokay essence or sausage. This essence is then put into casks, and preserved in very small quantity. The grapes are then put into a vat and trampled with the bare feet; to the squeezed mass is next added an equal quantity of good wine, which is allowed to stand for twenty-four hours, and is then strained. This juice, without further preparation, becomes the far-famed wine of Tokay, which is difficult to be obtained, and sells in Vienna at the rate of 5fl. per dozen. The Tokay vineyards are chiefly the property of the emperor.
In Denmark, notwithstanding the severity of the climate, they succeed in bringing to a tolerable degree of perfection most of the best sorts of fruits. Glass frames, portable canvas covers, and mats, are used to protect the blossom of the more tender trees against walls; and the harder sorts, as the apple and cherry, are, in spring, before the blossom expands, watered every night, in order at once to protect and retard it by an envelope of ice. This ice is again thawed off before sunrise by copious waterings.

225. The culinary vegetables of Germany are the same as those of Britain; but they are without the greater part of our best varieties. The Brassica tribe and edible roots arrive at greater perfection there than in France. The popular sorts are the field-cabbage and the bohereoles; they are used newly gathered, and boiled and eaten with meat, in broths or soups, and pickled in the form of sour kraut for winter use. The potatoe, kidney-bean, onion, and lettuce, are also in general use; and the first gardens possess all the olaceous and acaceous vegetables grown in France and Holland.

Subsect. 4. German Gardening, as to planting Timber-trees and Hedges.

226. Planting as a matter of profit has been little attended to in Germany from the number and extent of the native forests. In some districts, however, Pomerania for example, barren sandy tracts are sown with acorns and Scotch pine-seeds, chiefly for the sake of fuel and common husbandry timber. Much attention, as Emmerich informs us (Culture of Forests), and as appears by the number of German works on Forstwissenschaft, is in general paid to the management of forests already existing; as far as we have been able to observe, this extends to filling up vacancies by sowing, and occasionally draining and enclosing; thinning and pruning are little attended to in most districts. The oak, the beechn, and the Scotch pine, are the prevailing native trees of Germany.

227. Rows of trees along the public roads are formed and preserved with great care, especially in Prussia. The mulberry is the tree used in some of the warmer districts, and in other places the lime and the elm; the Lombardy poplar is also common near most towns of Germany, especially Berlin, Dresden, and Leipzig. Some attention is everywhere paid to public avenues; and the highways being, as in France, generally kept up by the government, improvements can be executed promptly and with effect. There being, in general, no accompanying hedges, and the trees being trained with naked stems to ten or fifteen feet high, according to the lowness or exposure of the situation, little injury is done to the materials of the road in wet weather. The breeze passes freely between the stems of the trees. The traveller and his horses or cattle are shaded during sunshine, and sheltered during storms; and the man of taste is furnished with a continued frame and foreground to the lateral landscapes.

228. Hedges, though not general in Germany, are used on the Rhine and in Holstein, the plants generally hawthorn, but sometimes hornbeam or a mixture of native shrubs. Hungary is the most backward province in respect to planting and hedges, as well as to every thing else. A hedge there is rare; and there are scarcely any public avenues beyond Presburg. Existing woods are subjected to a sort of management for the sake of the fuel they afford, and for their produce in timber and charcoal for the mines.

Subsect. 5. German Gardening, as empirically practised.

229. The use of gardens is as general in the best districts of Germany as in England; but in Hungary and some parts of Bohemia, Gallicia, and Prussia, many of the lower orders are without them, or if permitted to enclose a few yards of ground near their wooden hovels, they seem too indolent and indifferent, or too much oppressed by the exactions of their landlords, to do so. The cabbage tribe, and chiefly red greens, and the potatoe, are the universal plants of the cottage-gardens of Germany; lettuce, pease, onions, and turnips, with some other sorts, and the common fruit-trees, are introduced in some districts. Flowers are not very general, but the rose, thyme, and mint, are to be seen in many places, and a variety of ornamental plants in the better sort of cottage-gardens.

230. Farmer's gardens, as in most countries, are a little larger than those of the lowest class of cottagers; but inferior in point of order and neatness to that of the man who lives in his own cottage.

231. The gardens of the hereditary families are not, in general, much attended to; their appearance is too frequently that of neglect and disorder. Cabbage, potatoes, apples, and pears, and perhaps a few onions, are the produce expected from them; these are cultivated by a servant, not always a gardener, and who has generally domestic occupations to perform for the family. It will readily be imagined that, in such an extensive country, there are innumerable exceptions; in these, the gardens are better arranged, and the produce of a more varied description. Next to the gardens of the princes or rulers, the best are those of the wealthy bankers and citizens. These are richly stocked with fruit-trees, generally contain hot-houses, and are liberally kept up. Some of them contain collections of exotics. The best private gardens in Denmark belong to this class, and the remark will apply in the vicinity of all towns and cities in proportion to their rank as commercial places.
232. There are very few good gardens in Hungary; that of Prince Estehazy, the greatest proprietor of that country, is extensive, abounds in hot-houses, and contains a very full collection of plants. The prince has an English gardener, whom he sends frequently to this country to collect whatever is new.

233. The German princes and rulers are in general attached to gardens, and have very considerable ones at their principal residences; some of these have been mentioned, and various others might be added. These gardens are under the direction of intelligent men, who, in general, have spent part of their time in botanic gardens; and, in many cases, have studied or practised in Holland, or in the Paris gardens.

234. There are market-gardens near most large towns, but nurseries are much less common. There are extensive gardens of both sorts at Hamburg; but the best fruit-tree nurseries are supposed to be those of Sickler and Diel already mentioned. There is a good nursery at Wurtzburg, in Franconia, established by Meyer; one at Frankfurt on the Oder, and three at Vienna. In most places, the principal market-gardeners propagate a few fruit-trees for sale.

235. The operative part of gardening, in the better classes of gardens, is performed by men, who, agreeably to the general custom in Germany, not only served an apprenticeship, but travelled and worked for a certain time in different parts of the country, or of other countries.

The term of apprenticeship is three years and a half, and for travel three years, unless the apprentice is the son of a master-gardener; in which case, the term for travel is reduced to one year. All apprentices must be able at least to read and write, and are taught to draw, and furnished with written secrets in gardening by their master. During the term of apprenticeship, when that is completed, the youth is initiated into what may be called the free-masonry of gardening, and, being furnished with a pass-word, he proceeds from one town to another, till he can get work. Till this happens, his pass-word, and also a passport from the gardeners' society of the place where he was initiated, procures him, at every Gärtnerei herberge, or gardener's hostelry, lodging and food, and as much money as will supply his wants till he arrives at the next inn of a similar description. In this way he may walk over the whole of the German empire, Denmark, and a part of Holland, at the general expense; the numerous ramifications of the society extending over the whole of this immense tract. Such institutions exist for every trade in Germany, but being disliked by the governments, and being politically considered of an arbitrary and injurious nature, are now on the decline. On his return from probation, the travelled journeyman is entitled to take a master's place; and very commonly he continues travelling till he hears of one. The regular German gardener is a careful, neat-handed, and skilful workman; and, if allowed sufficient time, or assistance, will keep a garden in good order, and produce all the crops required of him in their proper seasons.

236. The artists or architects of gardens, in Germany, are generally the Land baumeister, or those architects who have directed their attention chiefly to country-buildings. Where only a kitchen or flower-garden is to be formed, an approved practical gardener is commonly reckoned sufficient. It occasionally happens, that a nobleman, who wishes to lay out an extensive garden, after fixing on what he considers a good gardener of some education, and capable of taking plans, sends him for a year or two to visit the best gardens of England, Holland, or France. On his return, he is deemed qualified to lay out the garden required; which he does, and afterwards attends to its culture, and acts as a garden-architect (Garten baumeister) to the minor gentry of his neighbourhood.

Subsect. 6. German Gardening, as a Science, and as to the Authors it has produced.

237. The Germans are a scientific people: they are a reading people, and in consequence the science of every art, in so far as developed in books, is more generally known there than in any other country. Some may wish to except Scotland; but, though the Scotch artisan reads a great deal, his local situation and limited intercourse with other nations, subject him to the influence of the particular opinions in which he has been educated: he takes up prejudices at an early period, and with difficulty admits new ideas from books. On the other hand, the Germans of every rank are remarkable for liberality of opinion: all of them travel; and, in the course of seeing other states, they find a variety of practices and opinions, different from those to which they have been accustomed; prejudice gives way; the man is neutralised; becomes moderate in estimating what belongs to himself, and willing to hear and to learn from others.

238. There are horticultural societies and professorships of rural economy in many of the universities; one or two gardeners' magazines, and almanacks of gardening; and some eminent vegetable physiologists are Germans. Even in Hungary, it appears (Bright's Travels), a Geographer, or college of rural economy, has been established by Graf Pestefits at Keszthely, in which gardening, including the culture and management of woods and copses, forms a distinct professorship. The science of France may be, and we believe is, greater than that of Germany in this art, but it is accumulated in the capital; whereas, here it emanates from a great number of points distributed over the country, and is consequently rendered more available by practical men. The minds of the gardeners of France are, from general ignorance, less fitted to receive instruction than those of Germany; their personal habits admit of less time for reading; their climate and soil require less artificial agency. The German gardener is generally a thinking, steady person; the climate, in most places, requires his vigilant attention to culture, and his travels have en-
larged his views. Hence he becomes a more scientific artisan than the Frenchman, and is in more general demand in other countries. Some of the best gardens in Poland, Russia, and Italy, are under the care of Germans.

239. The Germans have produced few original authors on gardening, and none that can be compared to Quintinie or Miller. They have translations of all the best European books; and so vigilant are they in this respect, that even a recent and most useful work on exotic gardening, by Cushing, hardly known in England, has not escaped the Leipsic book-makers. Hirschfield has compiled a number of works, chiefly on landscape-gardening; J. V. Sickler and Counsellor Diel have written extensively on most departments of horticulture, especially on the hardy fruits. (Sulzer’s Theory of the Fine Arts; Ersches Handbuch, &c. 2 Band. 1 Abth.)

SECT. V. Of the Rise, Progress, and present State of Gardening in Switzerland.

240. Extensive gardens are not to be expected in a country of comparative equalisation of property, like Switzerland; but no where are gardens more profitably managed or more neatly kept, than in that country. “Nature,” Hirschfield observes, “has been liberal to the inhabitants of Switzerland, and they have wisely profited from it. Almost all the gardens are theatres of true beauty, without vain ornaments or artificial decorations. Convenience, not magnificence, reigns in the country-houses; and the villas are distinguished more by their romantic and picturesque situations, than by their architecture.” He mentions several gardens near Geneva and Lausanne; Delices is chiefly remarkable because it was inhabited by Voltaire before he purchased Ferney, and La Grange and La Boissier are to this day well known places. Ferney is still eagerly visited by every stranger, but with the château of the Neckar family, that of the Empress Josephine, of Beauharnois, and others, eulogised in the local guides, present nothing in the way of our art particularly deserving of notice; though their situations, looking down on so magnificent a lake, the simplicity of their architecture, and the romantic scenery by which they are surrounded, render them delightful retirements, and such as but few countries can boast. The villa-gardens excel in rustic buildings (fig. 17.) and arbors; and are, for the most part, a mixture of orchards on hilly surfaces, cultivated spots, and rocks. However insignificant such grounds may look on paper (fig. 18.), in the reality they are pleasing and romantic. The public promenades at Berne are most beautiful, and kept with all the care of an English flower-garden. Switzerland has the peculiar advantage of producing a close turf, which in most places, and particularly at Lausanne and Berne, is as verdant as in England. Harte says great part of the Pays de Vaud is like the best part of Berkshire; and indeed every one feels that this is the country most congenial to an Englishman’s taste and feelings.

241. The first botanic garden which appeared in Switzerland was that of the celebrated Conrad Gesner, at Zurich, founded before the middle of the sixteenth century. He had not, Deleuze observes, sufficient fortune to obtain much ground, or to maintain many gardeners; but his activity supplied every thing, and he assembled in a small spot what he had been able to procure by his numerous travels and extensive correspondence. Public gardens were, in the end of this century, established at Geneva, Basel, and Berne, and subsequently in most of the cantons. The first of these gardens at present is that of Geneva, lately enlarged and newly arranged under the direction of that active and highly valued botanist, Decandolle. The garden of Basel is rich in the plants of all the mountainous regions which lie around it, including the Tyrol and Piedmont. A taste for flowers is perhaps more popular in Switzerland than in Germany; for though frugality is not less an object in every branch of rural economy, yet real independence is more gene-
GARDENING IN SWEDEN AND NORWAY.

rul; a poor man here, as Burns used to say, has generally some other estate than that of sin and misery; some little spot that he can call his own, and which he delights to cultivate and ornament. Speaking of Zurich, Simond observes (Tour, &c. 1819, p. 404.), "Haerlem excepted, there is not a town where more attention was ever paid to fine flowers: many new plants, as the Hortensia, Volkameria, &c., are here grown in perfection. The taste for flowers is particularly displayed on the occasion of the birth of a child. When the news is carried about to all the relations and friends of the family; the maid is dressed in her best attire, and carries a huge nosegay of the finest flowers the season affords.

242. Horticulture is carefully practiced in Switzerland; vineyards are formed as far north as Lausanne; and the apple, pear, plum, cherry, and walnut are common on every farm; the three first are in every cottage-garden. The filbert, gooseberry, currant, raspberry, and strawberry are natives; but only the filbert, raspberry, and strawberry are common in the woods and copses. In the sheltered valleys of this country, the apple and the pear are most prolific. Stewed pears is a common dish among the cottagers in autumn; the fruit is also dried, and in winter forms an excellent soup ingredient. The cabbage, the potatoe, the white beet grown for the leaves as spinach, and their foot-stalks as chard, and the kidney-bean for haricots and soups, are the popular vegetables. Particular attention is paid to bees, which are kept in neat rustic sheds (fig. 19.), or the hives carefully thatched with bark or moss.

243. There is little or no forest planting in Switzerland, but hedges of hawthorn are not uncommon. The walnut is there a very common high-road tree in the autumnal months, and furnishes the pauper traveller with the principal part of his food. Poor Italians have been known to travel from Naples and Venice to Geneva on this sort of fare. They begin with Indian corn and grapes, which they steal from the fields, till they arrive at Milan, and the rest of the road they depend on walnuts, filberts, and apples.

Sect. VI. Of the Rise, Progress, and present State of Gardening in Sweden and Norway.

244. Gardening is patronized by the higher classes, and practised round the principal towns of Sweden and Norway. "All the Swedes with whom I have ever met," observes Hirschfield, "whether elevated by birth, or enlightened by education, were estimable friends of beautiful nature and of gardens." Sir J. E. Smith (Lin. Trans., vol. i.) expresses an equally high opinion of this people. Mediocrity of circumstances, a poor court, political liberty, and a varied and comparatively unproductive country, seem to have contributed to give a more thinking turn to the Swedish nobles, than in countries naturally prolific. Their immense public works, canals, harbors, and excellent roads, careful agriculture, extensively worked mines, botanic gardens, literary institutions, and scientific authors are proofs of what we assert.

245. The ancient style of gardening appears to have been introduced to Sweden, at least previously to 1671; for Hermand, who published his Regina Suecia in that year, mentions the gardens of the palace as well as the Vivarium, or park. The gardens, he says, were used for delight and recreation. They lay between the Palatium and Vivarium, and the latter contained some wooden buildings, in which were kept lions, leopards, and bears. This garden and park appear to have been formed by Gustavus Adolphus, about 1620. Charles the Twelfth procured plans from Le Notre, and had the trees and plants sent from Paris. It is remarked by Dr. Walker, as a curious fact, that though the yew-tree is a native of Sweden, those plants of this species sent from Paris, to plant Le Notre's designs, died at Stockholm the first winter.

246. The mixed style is exemplified in Haga, formed on a rocky situation, about the middle of the eighteenth century, by Gustavus III., with the assistance of Masreter. It is the Trianon of Sweden. The approach is a winding walk through rocks and luxuriant verdure. Drottningholm is a royal palace, formed by the same prince on the island of that name. The gardens are in a sort of Anglo-Chinois manner, but as far as art is concerned, in no respect remarkable. Both these gardens are surrounded or intermingled with water, rocks, Scotch pine, spruce fir, and buildings, forming a picturesque assemblage of saxatile and verdant beauty. There are some confined spots laid out in the English taste, chiefly by British merchants in the neighbourhood of Gottenburg, as there are also near Christiana and Tranijem, in Norway; but it may be remarked, that this style is not likely to be generally adopted in either country, because they already possess much greater beauties of the same kind, which it is our aim to create, and with which those created would not bear a comparison.

247. A taste for flowers is not popular in Sweden; if a farmer or cottager has any spare room in his garden, he prefers rearing a few plants of tobacco. But the study of every branch of natural history is in repute among the higher classes and literati; and the co-
HISTORY OF GARDENING. PART I.

The botanic garden of Upsal was founded in 1657, under the auspices of King Charles Gustavus, and by the attention of Olaus Rudbeck. This learned man, seconded by the credit of the Count of Gardie, chancellor of the academy of Upsal, and who had himself a fine botanic garden at Jacobsdalh, obtained funds necessary for the construction of a garden and green-house, and to collect foreign plants; and he augmented its riches by the gift he made of his own garden in 1662. The progress of this establishment may be seen by comparing the three catalogues given by Rudbeck in 1658, 1666, 1685.

The latter enumerates 1870 plants, among which are 650 distinct species of exotics. (Bib. Bankston.) In 1702, the fire which consumed the half of the city of Upsal, reduced the green-house to ashes, and the garden was in a deplorable condition till 1740, when its walls were rebuilt. Two years afterwards the botanical chair and the direction of the garden were given to Linnaeus; and the university, undoubtedly excited by that reformer of natural history, took charge of all the necessary expenses for the acquisition and preservation of plants. Linnaeus, feeling how essential it was to be assisted in all the details of culture, obtained Diderich Nutzel, a clever gardener, who had visited attentively the gardens of Germany, Holland, and England, and who had then the charge of that of Clifford, in Holland. He there constructed new green-houses, intended for plants of different climates; and he solicited successfully the principal botanic gardens of Europe for specimens. Soon after, several of his pupils, whom he had excited with enthusiasm for botany, went across the seas to collect seeds and specimens; and many tropical plants, first grown at Upsal, were sent from thence to the southern countries of Europe.

The description and plan of the garden of Upsal may be seen in the Amoenitates Academicae. (Dissert. 7. t. 1. p. 171.) Linnaeus, in 1748 and 1753, published the catalogue of the plants cultivated there, and since his time, others have appeared, containing the additions which have been made by his successors. In 1850, the large orangery, built by Linnaeus, was found to be considerably out of repair, and was taken down and rebuilt. A magnificent lecture-room and museum was at the same time added. The ceilings of these rooms are supported by columns, which being hollow, are used as flues, and thus afford an elegant and effectual means of heating the air. On the whole, the garden is respectably kept up; and many hardy plants, natives of North America in particular, are found here in greater luxuriance than in France or Germany.

249. In horticulture the Swedes are considered as successful operators; but their short summers are adverse to the culture of many sorts of fruits and culinary vegetables in the open air; and there is not yet sufficient wealth to admit of forcing, or forming artificial climates to any extent. The apple, pear, and plum ripen their fruits in the best districts, especially in warm situations; but where the better varieties are grown, they are always planted against walls, and protected, as in Denmark. The Rubus chamaemorus, or cloudberry (fig. 20.), is very common in Lapland; its fruit is delicious, and sent in immense quantities, in autumn, from all the north of the Gulf of Bothnia, to Stockholm, where it is used for sauces, in soups, and in making vinegar. Dr. Clarke was cured of a bilious fever, chiefly from eating this fruit. There are a few forcing-houses near Gottenburg and Stockholm for peaches and vines; and one or two instances of pines being attempted in pits near the capital and in East Gothland. The borecole, red and green, the rutabaga and potatoe are the popular vegetables; but the best gardens have most of the Dutch and English varieties of the culinary tribe.

250. The towns and cities of Norway. Dr. Clarke informs us (Scandinavia, ch. 17. 1806), were formerly supplied with culinary herbs from England and Holland; but gardening became more general after the publication by Christian Gärter of a manual adapted to Sweden. Now all sorts of vegetables are common round Tronijem. The gardens of the citizens are laid out in the Dutch taste, and full of fruits and flowers. Of these are enumerated, apples, pears, plums, cherries, strawberries, cabbages, cauliflowers, turnips, cucumbers, potatoes, artichokes, lupines, stocks, carnations, pinks, lilies, roses, and many other garden-flowers. In the garden of the minister of Enontekis (fig. 21.), a village situated 287 miles north of Tornea, and perhaps the best garden in Lapland, Dr. Clarke found pease, carrots, spinach, potatoes, turnips, parsley, and a few lettuces. The tops of the potatoes were used boiled, and considered a delicate vegetable.
251. Planting is little wanted in Sweden, for seedling Scotch pines, spruce firs, and birch, rise up in abundance wherever old ones have been cut down. Enclosures in Sweden, as in Switzerland, are most frequently made of stone or of wood. Trees are planted along the roads in several places, and especially near Stockholm. The lime, the birch, and the ash, or trembling poplar, are the species used.

Sect. VII. Of the Rise, Progress, and present State of Gardening in Russia.

252. The history of gardening in Russia is very different from that of any of those countries which have yet come under review. Peter the Great sought, by one giant stride, to raise the character of his nation to a level with that of other countries; and, by extraordinary efforts, introduced excessive refinement amidst excessive barbarism; assembled magnificent piles of architecture in a marsh, and created the most sumptuous palaces and extensive parks and gardens, in the bleak pine and birch forests which surrounded it. As a man of Cronstadt rhymes,

"Built a city in a bog,
And made a Christian of a hog."

Nothing can be more extraordinary in the way of gardening, than these well-known facts, that a century ago there was scarcely such a thing, in any part of Russia, as a garden; and, for the last fifty years, there have been more pine-apples grown in the neighbourhood of Petersburg than in all the other countries of the continent put together.

Subsect. 1. Russian Gardening, as an Art of Design and Taste.

253. Russian gardening, as an art of design, began, like every other art, with Peter the Great. This emperor's first effort was made in 1714, when the garden of the summer-palace, on the banks of the Neva, in Petersburg, was laid out in the Dutch taste. But the grandest and most superb garden, in the geometric manner, is that which he constructed soon afterwards, about thirty wersts from the city, on the shores of the gulf. This imperial residence, as far as respects the gardens, has been justly called the Versailles of Russia; and the Prince de Ligne, an excellent judge, gives the preference to its water-works. The whole was originally designed and laid out by Le Blond, a pupil of Le Notre, and for some time court architect of St. Petersburg. This, with the other suburban palaces and gardens, have been minutely described by Georgi, and more generally by Storch, from whom we select the following outline:

254. Peterhof, in respect to situation, is perhaps unrivalled. About five hundred fathoms from the sea-shore this region has a second cliff, almost perpendicular, near twelve fathoms high. Bordering on this precipice stands the palace, thereby acquiring a certain peculiar prospect over the gardens and the gulf, to the shores of Carelia and St. Petersburg, and to Cronstadt. It was built in the reign of Peter the Great, by the architect Le Blond, but has received, under the succeeding monarchs, such a variety of improvements, that it has become a sort of specimen of the several tastes that prevailed in each of these eras, the influence whereof is visible in the numerous architectural ornaments, which are all highly gilt. The inside is correspondent with the destination of this palace; throughout are perceptible the remains of antiquated splendor, to which is contrasted the better taste of modern times. The gardens are more interesting by their peculiar beauties. The upper parts of them, before the land-side of the palace, are disposed into walks, plantations, and parterres, which acquire additional elegance by a large basin and canal, plentifully furnished with fountains of various designs and forms. The declivity before the back-front of the palace towards the sea has two magnificent cascades, rolling their streams over the terraces into large basins, and beneath which vast sheets of water, we walk as under a vault, without receiving wet, into a beautiful grotto. The whole space in front of this declivity, down to the sea-shore, is one large stately garden in the old-fashioned style, and famous for its jets-d'eau, and artificial water works. Some of them throw up columns of water, a foot and a half in diameter, to a height of two and a half or three fathoms. A pebbled canal, lined with stone, ten fathoms wide, running from the centre of the palace-façade into the gulf of Finland, divides these gardens in two. In a solitary wood stands the summer-house, called Monplaisir, which among other things is remarkable for its elegant kitchen, wherein the Empress Elizabeth occasionally amused herself in dressing her own dinner. In another portion of the gardens, close to the shore of the gulf, stands a neat wooden building, formerly a favorite retreat of Peter the Great, as he could here have a view of
Cronstadt and the fleet. The bath is likewise worthy of observation, situated in the midst of a thicket. We enter a large oval space, enclosed by a low wall, without covering at top, but open to the sky, and adorned with grottoes furnished with vases that all that convenience or luxury can require to that end. In the centre of this area is a large basin, surrounded by a gallery, and provided with steps, rafts, and gondolas: the water is conducted hither by pipes, which fill the last-mentioned basin, the water-works still exist, and the vases are kept in tolerable repair. There is adjoining a small specimen of English gardening, laid out by Meader, once gardener at Alnwick castle in Northumberland, and who is author of _The Planter’s Guide._

255. At Petrovka, near Moscow, is the principal private ancient garden in Russia. The hedges and alleys are chiefly formed of spruce fir, which are shorn, and seem to flourish under the shears. It contains also a labyrinth, and a turf amphitheatre, on which the proprietor, Comte Razumowski, had operas performed by his domestic slaves.

Sophiska, in Podolia, is a magnificent residence of the Countess Potocki, laid out by a Polish architect, Metzel, in the manner of Sweritz. It has a magnificent terrace or promenade, and extensive avenues, conservatories, and gardens.

256. The first attempt at the modern style of gardening in Russia was made by Catherine, about 1778, at Zarskoje-selo, at that time enlarged and re-laid out. The gardener employed was Busch, a German, and father of their present superintendent. The gorgeous magnificence of this residence is well known. “A natural birch forest, on ground somewhat varied, forms the ground-work of the park and gardens. The gate by which they are approached, is an immense arch of artificial rock-work, over which is a lofty Chinese watch-tower. The first group of objects is a Chinese town, through which the approach leads to the palace; a building, which, with its enclosed entrance, court, offices, baths, conservatories, church, theatre, and other appendages, it would seem like exaggeration to describe. The rest of the garden-scenery consists of walks, numerous garden-buildings, columns, statues, &c. with bridges of marble and wood, a large lake, and extensive kitchen-gardens and hot-houses.” The following more detailed description is from the pen of Storch already mentioned.

257. Zarskoje-selo, the famous summer-residence of Catherine the Second, is situated in an open pleasant region, diversified by little hills, meads, and woodlands. The space of the whole domain contains four hundred and twenty thousand square fathoms. This princely seat owes its origin to Catherine the First, and its enlargement and embellishment to Elizabeth; but it is indebted for its completion in elegance and taste, and the greater part of its present magnificence, to the creative reign of Catherine the Second. We are now in a small wood within sight of the palace. On the left we have the park wall, and before us the entrance on the Petersburg side. It consists of two portsals, composed of blocks of sandstone, in the form of rocky fragments, over one of which is a Chinese watch-house. By this passage we enter the grounds of the palace, having thus the right, and a Chinese bridge is left, through which the way leads over a Chinese bridge to the park. Before us lies the road to the little neighbouring town Sophia, which goes through a colossal gate of cast-iron. The court of the palace forms an amphitheatre of buildings opposite the grand parade, closed on each side by an iron palissade.

The gardens are laid out in the English manner: among their curiosities that admit of a description, the following objects may principally be recorded. A small temple containing a collection of antique and modern statues; a solitude for dinner-parties like that in the hermitage; a magnificent bath; a coach-hill, similar to that at Oranienbaum; picturesque ruins; a small town to commemorate the taking of Taurida, &c. Two artificial lakes are connected by a running stream, crossed by an arch and bridge, covered at the top by a roof resting on two rows of marble columns, on the model of the bridge at Stowe. On one of the islands on these lakes stands a Turkish mosque, on another a spacious hall for musical entertainments. In a thick shrubbery is a pyramid, in the form of an Egyptian obelisk. This majestic sanctuary of art and nature, continues Storch, is at the same time a magnificent temple of merit. Formed of the rocky foundations of the earth, here the monuments of great achievements tower towards the skies, by the side of the domestic achievements of the ancients. Marble obelisks remind us of the victory near Kagul, and of the victor Romanoff Zudunalsky. To the Day of Tschehimi, and the hero Orlof Tschesmensky, a marble column on a pedestal of granite is devoted. A grand triumphal arch proclaims the patriotic ardor of Prince Orlof, with which he faced rebellion and the plague in the capital, and quelled them both. The victory in the Morea and the name of Fendor Orlof are handed down to posterity by a rostral column.—Plain and gigantic as the sentiments of the heroes whose memories are perpetuated in these masses of rocks, they stand surrounded by the charms of Nature, who softens her majesty through the veil of artless graces.

258. Paulovsky presents the best specimen of the English style, in the neighbourhood of the Russian capital, or indeed in the empire. It was begun during the reign of Catherine, in 1780, from a design said to have been furnished by the celebrated Brown, from a description sent him by Gould, an Englishman, the gardener of Potemkin, and finished afterwards during the reign of Paul. This place possesses considerable variety of surface, and a varied clothing of wood, the Scotch pine and aspen being natural to these grounds, as well as the birch. Near the palace, there is a profusion of exotics of every description, including a numerous collection of standard roses, which, with some of the American shrubs, require to be protected with straw and mats during winter. The Chevalier Storch has given a very interesting description of these gardens, in his _Briefe iiber Paulovsky,_ &c. 1802.

259. The gardens of Potemkin, a man whose mind, as the Prince de Ligne has observed, contained mines of gold and steppes, and one of the most extravagant encouragers of our art that modern times can boast, were of various kinds, and situated in different parts of the empire. The most extensive gardens of this prince were in the Ukraine; but the most celebrated were those belonging to the palace of Taurida, now an imperial residence in St. Petersburg. The grounds are level, with several winding and straight
part of the building is that of a semicircle, embracing the end of a saloon, nearly 300 feet long. It is lighted by immense windows, between columns, has an opaque ceiling, and is at present heated by common German stoves. It is too gloomy for the growth of plants, but those grown in the glass sheds of the kitchen-garden are carried there, sunk in the ground, and gravel-walks, turf, and every article added, to render an illusion to a romantic scene in the open air as complete as possible. The effect was, after all, it is said, never satisfactory but when illuminated. This palace, the original exterior of which was in a very simple style, and the interior most magnificent, is said to have been the design of Potemkin, but it was entirely re-modelled at his death by Catherine, used as barracks by Paul, and is now very imperfectly restored. (Ed. Encyc. art. Landscape Gardening.)

This winter-garden or conservatory, so much spoken of, is thus described by Storch: "Along one side of the vestibule is the winter-garden, an enormous structure, disposed into a garden, only separated from the grand hall by a colonnade. As, from the size of the roof, it could not be supported without pillars, they are disguised under the form of palm-trees. The heat is maintained by concealed flues placed in the walls and pillars, and even under the earth leaden-pipes are arranged, incessantly filled with boiling water. The walks of this garden meander amidst flowery hedges, and fruit-bearing shrubs, winding over little hills, and producing, at every step, fresh occasions for surprise. The eye of the beholder, when weary of the luxuriant variety of the vegetable world, finds recreation in contemplating some exquisite production of art: here a head, from the chisel of a Grecian sculptor, invites to admiration; there a motley collection of curious fish, in crystal vases, suddenly fixes our attention. We presently quit these objects, in order to go into a grotto of looking-glass, which gives a multiplied reflection of all these wonders, or to indulge our astonishment at the most extraordinary mixture of colors in the faces of an obelisk of mirrors. The genial warmth, the fragrance and brilliant colors of the nobler plants, the voluptuous stillness that prevails in this enchanted spot, lull the fancy into sweet romantic dreams; we imagine ourselves in the blooming groves of Italy; while nature, sunk into a death-like torpor, announces the severity of a northern winter through the windows of the pavilion. In the centre of this bold creation, on a lofty pedestal, stood the statue of Catherine II., surrounded by the emblems of legislation, cut in Carrara marble. It has been thrown out of the building on its being made into barracks."

The gardens at Potemkin's other residences, as well as many imperial and private gardens in Russia, were laid out by Gould, a pupil of Brown. Sir John Carr relates an anecdote on Gould's authority, which was confirmed to us, in 1813, by the present gardener, Call, his successor, and deserves a place here. In one of the prince's journeys to the Ukraine, Gould attended him with several hundred assistants, destined for operators, in laying out the grounds of Potemkin's residence in the Crimea. Wherever the prince halted, if only for a day, his travelling pavilion was erected, and surrounded by a garden in the English taste, composed of trees and shrubs, divided by gravel-walks, and ornamented with seats and statues, all carried forward with the cavalcade. On another occasion, "having accidentally discovered the ruins of a castle of Charles XII. of Sweden, he immediately not only caused it to be repaired, but surrounded by gardens in the English taste." (Carr's Battle, &c.)

260. The most extensive seats laid out in the modern style, in the neighbourhood of Moscow, are those of Gorinka, a seat of Count Alexy Razumovsky (fig. 23.), and Petrowka, a seat of Petrowsky Razumovsky. The former is remarkable for its botanical riches, and an immense extent of glass. The grounds are of great extent, but the surface flat, and the soil a dry sand. A natural forest of birch and wild cherry clothes the park, and harmonises the artificial scenes. The mansion, built by an English artisan, is highly elegant; and the attached conservatories and stoves, and decorated lawn, form a splendid and delightful scene, unequalled in Russia.
261. *Petrouka* contains both an ancient garden, already referred to, and a large extent of ground, laid out in the modern style, and adorned with buildings, from designs by Signor Camporezi. There is some variety of surface, abundance of birch and fir woods, with some oaks and aspens interspersed, and a large piece of water. Among the ornamental buildings is a cotton-manufactory, in actual use as such. The practice of introducing manufactories as garden-buildings, is very general in Russia, and almost peculiar to that country.

262. Among other gardens near Moscow may be mentioned those of Count Alexy Razumowsky, and of Paschow, in Moscow; of Zaritza (fig. 24.), a singular Turkish palace, built by Potemkin for Catherine; of Astankina Count Chéraméto, Feckra, Prince Galitzin, and various others, which would well bear description. In general, extent, exotics, and magnificent artificial decorations are more the object of the modern style in Russia, than scenes merely of picturesque beauty. We think this may be accounted for, partly from the general want of refinement of taste in that country, and partly from its inaptitude for that style. The nobles of Russia, suddenly rendered aware of being distanced in point of civilisation by those of most other European countries, are resolved not merely to imitate, but even to surpass them in the display of wealth. The most obvious marks of distinction, in refined countries, are necessarily first singled out by rude and ambitious minds, and large magnificent houses and gardens are desired, rather than comfortable and elegant apartments, and beautiful or picturesque scenes; since, as every one knows, it is much more easy to display riches than to possess taste; to strike by what is grand, than to charm by what is beautiful.

263. Around Petersburg and Moscow are several public gardens and various private ones, which their owners, with great liberality, convert into places of public entertainment, to which all the people of decent appearance are at liberty to come. The country-seats of the two brothers Nariskin deserve our particular notice, as being frequented on Sundays by great numbers of the higher classes. A friendly invitation, in four different languages, inscribed over the entrance to the grounds, authorises every one, of decent appearance and behaviour, to amuse himself there in whatever way he pleases, without fear of molestation. In several pavilions are musicians, for the benefit of those who choose to dance; in others are chairs and sofas, ready for the reception of any party who wish to recreate themselves by sedate conversation, after roaming about with the great throng; some parties take to the swings, the bowling-green, and other diversions; on the canals and lakes are gondolas, some constructed for rowing, others for sailing; and if this be not enough, refreshments are spread on tables, in particular alcoves, and are handed about by persons in livery. This noble hospitality is by no means unenjoyed; the concourse of persons of all descriptions, from the star and riband, to the plain well-dressed burgher, forms such a party-colored collection, and sometimes groups so humorously contrasted, that for this reason alone it is well worth the pains of partaking once in the amusement. (*Storch's Petersburg*, p. 441.)

264. In the country parts of Russia, hundreds or even thousands of miles may be gone over without meeting with any country-seat worth mentioning. The nearest to Moscow, southwards, which we have seen, is that of Sophiowski, in Podolia, 1000 wersts distant.
SUBSEC. 2. Russian Gardening, in respect to the Culture of Flowers and Plants of Ornament.

265. Dutch flower-roots, would doubtless be introduced in the imperial gardens with the Dutch taste in design; and soon after copied by such of the nobility as could afford to copy in matters of this kind. It was reserved, however, for Catherine the Second to give the first impulse to this taste, by establishing at Petersburgh, the first public botanic garden in 1785, for the use of the academy of sciences. Another was soon after formed for the medical college.

266. The botanic garden of the university of Moscow was founded by the present emperor, in 1801, but was unfortunately destroyed by the French in 1812; at which time the university was burned down. Both, however, are now restored to their original splendor.

267. The first private botanic garden formed in Russia was that of Count Dimidow, begun during Peter the Great's reign. It was chiefly devoted to native plants; but still the hot-houses for exotics occupied more than one acre of ground. Two botanists were sent to travel over the whole of Asiatic Russia. In 1786 a catalogue was published, when the collection amounted to 4363 species or varieties, exclusive of 572 varieties of fruit-trees, 600 varieties of florists' flowers, and 2000 species which had not flowered. "Une seule anecdote," says Deleuze, "will prove how eager Dimidow was to enrich his garden. Being at Rome, in 1773, he found in the garden of the Petits Augustins del corso, the handsomest orange-tree he had ever seen. The monks did not wish to part with it, and he was obliged to employ a good deal of money and influence to overcome their scruples. Having succeeded, he caused the tree, which was planted in the open air, to be taken up with an immense ball, put in a large box, set on a carriage made on purpose, and transported to Moscow." (Annales, &c. tom. ix. 174.)

268. The botanic garden of Gorinka, already mentioned, presents the most extensive private establishment not only in Russia but perhaps in the world. The great extent of glass has been already mentioned. When we saw these hot-houses, in 1814, they were much injured by the French; but the whole garden is now, we understand, completely reinstated. Dr. Fischer, its director, is a well known botanist, and corresponds with most botanical cultivators in Europe. A catalogue of this garden was published by Dr. Redowsky, in 1804. (Bib. Banks.) Its proprietor having lately died, this garden will probably share the fate of many others.

There are other private botanic gardens near Petersburg and Moscow; and good collections of ornamental plants at Pawlowsky and Gatchina, both imperial residences. The Baron Rahl has an extensive range of hot-houses, devoted chiefly to orange-trees and tender plants; and many of the Dutch and German merchants cultivate flowers in the gardens of their summer-residences, on the Strelna road, at Petersburg. Excepting however among the first of the nobility, and the wealthy foreign merchants, ornamental culture of every description is quite unknown in Russia. The taste of the ordinary nobleman is too gross; the peasant is out of the question, and there is no middle class in the empire of the Tzars.

269. The climate of Russia is adverse to floriculture. Dr. Howison remarks (Caled. Mem. iii.), "that there is scarcely any plant, or flowering shrub, which can resist the intense frost and cold of the winter in Britain, to be found out of doors in Russia; and, at times, even the hardy whin-bush is destroyed." He says, the gardener, in the Tauridon palace, Call, showed him "I'llac-trees, laburnums, different varieties of thorn, whin-bushes, &c. growing in large wooden tubs, filled with earth, and which were preserved there all winter, with the intention of being sunk in the borders of the garden, as soon as the weather should grow warm enough to admit of it. In the gardens of the villas and country-houses of the higher classes of Russians and foreigners settled in the country, in the short period of a week from the disappearance of the winter, a beautiful and rich display of shrubs and flowers in full blow, consisting of hydrangeas, various species of geranium and myrtle, wall-flower, carnation, &c. become visible. All these are, in like manner, reared in hot-houses. As their bloom fades, fresh plants are brought from the conservatory to replace them, thus keeping up an artificial garden, as it may be called, during the whole warm season; and when the cold weather begins again, the whole are removed and replaced in the green-house."

SUBSEC. 3. Russian Gardening, in respect to its horticultural Productions.

270. Dutch and German fruits were introduced to Russia with the Dutch and French taste in gardening, by Peter the Great. With the English style, Catherine introduced English gardeners and English fruits. Before this period, the wild pear, the wild cherry, the black currant, the cranberry, and the strawberry must have been almost the only fruits seen in aboriginal Russia; all these may be gathered in the woods. The apple is abundant in the Ukraine, and a century ago, as at present, may have been sent to Moscow for the use of the higher classes. At present, the imperial family, and a few, perhaps six or eight of the first nobility, enjoy almost all the European fruits in tolerable perfection, chiefly by the influence of glass and fire heat. The quantity of pines and grapes grown in the neighbourhood of Petersburg, is indeed an astonishing feature in its
HISTORY

thus and onions, but and every elsewhere

feature they vandalized, some and

Petersburg enjoyments in man, the room in the century, is nobleman can taste are the wild pear (grouthchy), dried or green, the strawberry, and the cranberry. Of the last, a cooling acid beverage is made by infusion in water.

272. If any culinary vegetables were known in Russia, before the beginning of the last century, it could only have been the dwarf, ragged-leaved brown kale and the mushroom; the potato is but lately introduced, and that only in a few places. Many of the peasants refuse to eat or cultivate this root, from mere prejudice, and from an idea very natural to a people in a state of slavery, that any thing proposed by their lords must be for the lord’s advantage, and not for theirs; thus the first handful of food thrown to untamed animals operates as a scare.

The example of the court, and the number of foreigners employed in the Russian service, civil and military, in their literary institutions, and established as medical or commercial men in the towns, will, no doubt, gradually introduce a variety of culinary plants. The late war may also have had some influence, by giving the, till then, untravelled noble a taste for the comforts of Germany and France; but, unfortunately, the Russians are averse to a country life, and will continue to be so till they acquire a taste for domestic employments and rural recreations. Dr. Horrow in (Mem. of Caled. Hort. Soc. vol. iii. 77.) has given “an account of the most important culinary vegetables cultivated in the interior of the Russian empire.” Of these, the cucumber, melon, yellow turnip, radish, and bulbous celery, were introduced from Germany, and are known but to a few. The remaining sorts mentioned are, the variegated cabbage, introduced from the South Sea Islands; mustard, from Sarpeka, near the Chinese wall; and an onion from Chinese Tartary. These were introduced by Hasenkampf, of the late Russian embassy to China. The English and German court-gardener grow abundance of all our best vegetables, and continue to prolong the season of some of them, as cauliflowers, celery, cabbage, &c. by earthing them in cellars. A succession of salading is kept up in hot-houses, during winter, and even the first crops of all the common oleraceous and acetaceous plants are reared under glass and by fire heat in some of the best gardens. In Storck’s Petersburg (chap. iv.), the dependence of Russia on foreign countries for her culinary vegetables and fruits is amply detailed. In the Crimea, according to Mary Holderness, horse-radish, asparagus, carrot, dock, sorrel, nettles, capers, and mustard, are gathered wild, and used as pot-herbs. Cabbages are cultivated, and they attain a great size: onions, pompions, water-melons, and capsicum, are also grown. (Notes, &c. 152.)

SUBSECT. 4. Russian Gardening, in respect to the Culture of Timber-trees and Hedges.

273. Forest or hedge planting is scarcely known in Russia. There are yet abundance of natural forests for timber and fuel, and in the northern parts where no system of pasturage can take place, enclosures are not now, and probably never will be, of any use. Hedges are in use in the gardens of the capital, and of the city of residence. The time is not yet come for planting the sides of the high-roads, though that would be a grand feature of improvement. In some governments, towards the south, this has been partially done in a few places, by stakes of the silvery-leaved, or Huntingdon willow (Salix alba), but the trembling poplar, birch, and lime, are the proper trees for the northern parts, and the cherry, alder, sycamore, oak, elm, walnut, &c. may be introduced in advancing southwards.

SUBSECT. 5. Russian Gardening, as empirically practised.

274. The very limited use of gardens in this country has already noticed. Few are to be seen attached to the isbas, or log-houses of the boors, and not many to the rich privileged slaves, or the native freedmen of the towns. There is no such thing as a Russian farmer; every proprietor farms the whole of his own estate by means of his slaves and an agent. The greater part of these proprietors have no gardens, or if they have, they are wretched spots, containing a few bocoreles, and but rarely potatoes or legumes. The use of gardens is, therefore, almost entirely confined to the imperial family, the highest class of nobles, and a few foreigners, who have settled in the principal cities.

275. There are nurseries established in different districts by government, especially in Courland and the Ukraine. In the Nitika nursery, in the Crimea, apple, pear, peach, almon, vine, fig, olive, and pomegranate plants are propagated under Stevens, a German, and sold at low prices.
276. The head operative gardeners of Russia are almost all foreigners or sons of foreigners. Sometimes a nobleman sends a slave as an apprentice to a gardener, for his own future use; but generally the assistant labourers are mere Russian boors, slaves of the lord; or other slaves who have obtained permission to travel and work on their own account for a few years. These boors make very tractable labourers; for the Russian is imitative and docile, to a high degree. They require, however, to be excited by interest or fear. The freed slaves on the government estates in the Ukraine, Mary Holderness informs us (Notes on the Crimea, &c. 1821.), dig sitting and smoking.

277. The garden-artists of Russia are the English or German head-gardeners attached to the establishment of the emperor, or of some eminent noble. Gould, Potemkin's gardener, was the Brown of Russia in Catherine's time. This man had a character in some degree analogous to that of his master; he lived in splendor, kept horses and women, and gave occasionally entertainments to the nobility. A few years ago he returned to England, and died at an advanced age in 1816, at Ormskirk in Lancashire, his native town.

A foreigner once established as head-gardener to the emperor, or any of the first nobility in Russia, becomes in some degree a despot, like his master, and unless he commits very gross errors indeed, his conduct is never enquired into, nor does he lose his place but with life, or return home. He is not very literally paid, but he enjoys every comfort of the state of society there affords; lives in a house that would be reckoned a considerable mansion in England, and has abundance of servants, and a carriage and horses, at his command. His country, and its broad cloth, procure him the respect of the nobles, and the dread of the slaves; the former he may render tributary by presents of seeds, and the latter he may kick and beat at pleasure. If at any time he goes too far, a few radishes to the police-bailiffs, or a few peaches, or a melon, to the chevaliers their masters, will restore every thing to harmony.

SUBSEC. 6. Russian Gardening, as a Science, and as to the Authors it has produced.

278. Science of every kind stagnates in Russia. However adroit the foreign gardeners may be, in adapting practices to the climate, it can hardly be expected, in the circumstances in which they are placed, that they should increase the knowledge brought with them. Separated from their friends, surrounded by strangers using a language with which they never become familiar, without the means of procuring new books, and rarely coming in contact with intelligent gardeners or naturalists; much of the knowledge they carried with them, is unavoidably forgotten or neglected. We regret to add, that it has been remarked by various travellers, that even the moral sense of Englishmen, who settle in Russia, becomes in time contaminated by the baneful influence of Russian manners. The want of common honor and honesty which pervades all ranks of the natives in Russia, from the first minister to the meanest slave, is incredible. One wonders at first, how such an immoral state of society can exist; but the refined moral habits of civilised nations, like their refinements in cookery and dress, may all be traced to the simple principle of self-preservation: and as a savage can put up with a homely fare and a coarse garb, so it would appear a barbarous people may hang together by a sort of tattered moral principle.

279. We know of no original Russian author on gardening. There is a poem, On Gardens, by Samboursky, translated into the French language by Masson de Blamont: there is also a poem on glass, by the Russian poet Lomanosow, which, as containing a eulogium on hot-houses, may be considered as belonging to this subject. Some translations have been published in German; and various papers on botanical, physiological, and agricultural subjects, appear from time to time, in the Transactions of the Imperial Economical Society.

SECT. VIII. Of the Rise, Progress, and present State of Gardening in Poland.

280. Gardening, as an art of design, was introduced into Poland by the electoral kings about the end of the seventeenth century, and especially by Stanislaus Augustus, the third elector.

281. In respect to gardens in the geometric style of design, the most ancient royal example is the Jardin Electoral de Saxe. It was never completed, and is now a public garden. Le Jardin Kazinski is another public garden; but by far the most remarkable is that of Lazienki, or the Bath, formed by the last king; on the site of an ancient park, at Ujaszlow, within the suburbs of the city. At the beginning of the reign of Stanislaus, in 1764, it was a marshy wood, planted with alders, with some canals and other stagnated pieces of water, near which was a grotesque edifice, called the Bath, and from which this park takes its name.

The palace of Lazienki (fig. 25), a beautiful piece of Roman architecture, from the designs of Campiter, a German artist, is placed on an island in a considerable piece of water. It consists of a centre and two wings. The centre is placed in the middle of a narrow part of the lake, and the wings are on opposite shores, and joined to the centre by arches with orangeries over. The entrance is by a carriage-portoico, in one of the wings, to which you arrive without seeing the lake; and on entering the orangerie, its first effect is surprising and delightful. On the north shore of this lake is an open amphitheatre of stone with its orchestra on the brink of the water; and near the margin an island of trees, which served as the presen- nium. This theatre was at all times open to the public; and in addition to the ordinary exhibitions, ships and naval engagements were occasionally exhibited. The gaiety which reigned here during the first years of the reign of Stanislaus, the singular effect of the illuminations, the ships, and the resounding of the music.
in the woods, are still recollected by some of the oldest inhabitants of Warsaw, and spoken of with feelings of regret. The grounds were not extensive, nor, excepting near the palace, much ornamented: they consisted of a number of broad green alleys, crossing each other at right angles; of smaller covered paths, leading to open circles of turf for dances and music, and for tents and booths on extraordinary occasions. In several places coffee-rooms and ice-cells were established, and still remain; and there are two pavilions for the king's mistresses; and another, which served as a seraglio, for strangers or visitors of the king: the three being connected with the palace by arbor-like paths, or arcades of trellis work, covered by creepers.

One thing deserves to be remarked as to these gardens, which is, perhaps, not to be found in any others in Europe. Pedestals, as if for placing statues, were ranged in different parts of the grounds, particularly along the broad walk leading from the palace to the amphitheatre. On these pedestals, on extraordinary occasions, selected living figures, male and female, dressed in character, were placed, and taught to maintain certain attitudes, after the manner of the representations called Tableaux, and which are sometimes, though rarely, produced in private circles at Paris and Vienna on days when theatrical amusements are forbidden. It is not to be wondered at that so luxurious a king should have wanted decision of character, lost his honor, kingdom, and, in short, every thing worth having. In 1815 this seat was nearly in the state in which it was left by Stanislaus; but we understand it has since undergone several changes.

282. The principal private garden in the ancient style was that of Villaneuve, the property of Count Stanislaus Potocky, a few miles from the capital, but now modernised. Judging from the excellent views of these gardens, painted by B. Canaletts, and now in the zamok, or castle, in Warsaw, they must have been elegant of the kind. At Cracovie there are the remains of a geometric garden, of a few acres, laid out by Marshal Loudon, when Austrian governor of that city; one of a convent of some extent, and a small public garden. But in the south of Poland, and especially in Gallicia, the only thing remarkable as to design in gardens, is the powerfully walled enclosures of the convents and religious houses, in some of which are venerable orchards, broad grass-walks, mossy trees, and curious sun-dials.

283. English gardening was introduced into Poland by the Princess Isabella Czartoryska, at Pulhawa. This lady, highly accomplished, of great taste, and much good sense, had been a considerable time in England. She carried to Poland a gardener, Savage, and with his assistance, and that of Vogel and Frey, artists of Warsaw, she laid out Pulhawa, between 1780 and 1784, and published in Polish (Mysli Rosne o Sposobie Zakladania Ogradow) a work with plates, on English gardening, in 1801. The situation of Pulhawa, like almost every other with which we are acquainted in Poland or Russia, is flat and sandy; but is somewhat relieved by the Vistula. On the brink of this river, on a wooded bank, stands the house, a plain Grecian building, which with the grounds are described by Burnet, in his view of Poland. (chap. xi.) There are several decorative buildings, and statues (fig. 26.); detached clumps of shrubs are more frequent in these gardens than would be admitted by a good taste in England; but all Poland is a natural forest; and as the grand object of improvement in every country, is to obtain applause by the employment of art and expense, artificial forms, from their rarity, are better calculated for this purpose than such as are more universally beautiful, but so common locally as to want the charm of novelty,—or whose beauties are too refined to be generally understood. Thus clumps in Poland may be as much esteemed as groups are in England, on the same principle, that, in a wild country, butcher-meat is more esteemed than game, because the latter is the common food.

Zamoyski the seat of Count Zamoski, and Villanueve the residence of Count Potocky, are also examples of the modern style. The first are of limited extent, but the latter, near Warsaw, are very extensive, and were laid out chiefly from the designs of Princess Czartoryska.

The gardens of General Benningsen, near Wilna, were in a mixed style, surrounded by oak and pine forests. They were destroyed during the retreat of the French army in 1812.

Thus of Colonel Laschutski, at Pontenavia, on the banks of the Niemen, at Grodno, are not extensive, but contain more romantic and picturesque scenery than any garden we have seen in Poland.

284. The oldest botanical garden in Poland is that of Wilna, founded by Catherine, soon after the dismemberment of that country; the most thriving is that of Cracovie, placed in 1812 under the direction of Professor Oestricher, a zealous botanist. A garden was also begun about 1810, in Warsaw, on the steep banks of the Vistula. Of the original
Warsaw garden, of which a catalogue was published towards the middle of the last century, we could, in 1813, procure no account. Count Benningsen had an excellent botanic garden at his seat near Wilna, which, as already observed, was destroyed and the château burned down in 1812. It was rich in hardy plants. At Pulhawa the Princess Isabella Czartoryska has a considerable collection, and used frequently to send her gardener (Savage), lately deceased, to England to procure the newest exotics.

285. A few flowers are cultivated in some of the wealthier citizens' gardens, around Warsaw, and a few in gardens of the conventual institutions; but in a general point of view, they are as uncommon in Poland as in Russia. In both countries a few may occasionally be seen on market-days, which have been gathered in the fields, and brought in by the peasants; these are purchased by the minor nobles to decorate their rooms, by the monks to display on their altars, or by devotedes to present to the virgin or the image of their patron saint. The floors of the higher classes, in Poland, are often strewn with the leaves of the Acorus calamus, which abounds in the marshes of that country. In some districts, towards Courland, the spray of the spruce fir is used for this purpose; a practice, as Mary Woolstonecraft has remarked, common in Sweden and Norway.

286. The horticulture of Poland is at a very low ebb: excepting in a few of the noblemen’s gardens and those of the richest monasteries, there was till lately no vegetable but the kohl rabi, and no fruit but the apple, pear, and cherry. Towards the sea-coast, and on the borders of Austria, there is greater variety. The potatoe is now in more general use in Poland than in Russia, though a slight prejudice still exists against it, from its having been introduced by the Germans. The cucumber is cultivated in many places for salting, or preserving by barrels and sinking the barrel in their wells. In some places, the common carnation poppy is grown for the seed, which taken when beginning to ripen, and strewed on the floor of milk-porridge, or milk-paste, made from the meal of buckwheat, or Polish millet (Dactylion sanguinale), is reckoned a delicacy. Bees are kept by some of the freed men or minor nobles. The Polish hives and mode of taking the honey, to be afterwards described, are exceedingly simple, and never requiring the death of the insects, seem preferable to any mode of bee-culture yet devised by the bee-masters of other countries. Hirschfield mentions, that the gardens of Prince Casimir Poniatowski, elder brother of the last king, contained at one time 5000 annasans, in a range of hot-houses 600 feet long. In 1813, the only pines grown in Poland, were a few at Pulhawa, and some grown by a German, who rented the hot-houses belonging to the late king’s establishment at Warsaw. Only one or two instances then existed of vines and peaches being grown near the capital, but there were abundance of these and other fruits at Pulhawa and Zamost, and some few at Villaneuve. The Polish noblemen have gained in every kind of knowledge from having been so long a period in the French service; and since the re-establishment of peace, they have set about agricultural and gardening improvements, with a considerable degree of energy.

287. Planting in Poland is but little required for purposes of utility. Some public avenues have been formed near Warsaw and Posen: and the elm, one of the best avenue trees, thrives at both places. There are scarcely any hedges in the country, excepting in gardens and near towns.

288. Original Polish authors on gardening are not to be expected: but translations of various works on rural economy were pointed out to us in the library of the Dominicans, at Grodno; but the only Polish work on gardening, which may be considered as original, we believe to be Mysli Rozone o Sposobie Zabudowania Ogrodów, &c. 1808; or, "Various Thoughts on the Manner of planting Gardens," by Princess Isabella Czartoryska.

Sect. IX. Of the Rise, Progress, and present State of Gardening in Spain and Portugal.

289. The love of gardens, or of rural life, it is alleged by Hirschfield, is far from being general in Spain: not however from lightness of character or bad taste, but from a kind of supineness which cannot be better described than by calling it Spanish. This supineness is the more incomprehensible, as the country, though desert and uncultivated in many places, is yet full of natural charms in others, thus indicating as it were a field of exertions for the hand of man. In many provinces, Puente informs us, one may travel several leagues without seeing a tree, and according to the same author, the environs of Madrid neither present pavilions nor country-houses, and it was not till towards the end of the eighteenth century that they began to repair the roads around the capital, and border them with trees.

290. The Arabs of Spain attended to agriculture, translated and commented on the ancient authors, and though they occupied themselves more particularly in the study of medicine and botany, they did not neglect the culture of gardens. Many of them travelled to their brethren in Asia, to pursue natural history, and bring plants to Europe. Ebn-Alwan has left us a list of plants in the garden of Seville, in the eleventh century,
which are more numerous than those which were cultivated by the Greeks and Romans. The recent substitution of a representative for a despotic government, so happily brought about (1820), can hardly fail of acting as a stimulus to exertion in art, in common with every other.

Subsect. I. Spanish Gardening, as an Art of Design and Taste.

291. The oldest garden in Spain is said to be that of the Moorish palace of Alcazar, near Seville; the greater part of this palace was constructed by Peter the Cruel, between the years 1353 and 1364, who exactly copied the Arabian style of the ancient part of the edifice; and the remainder was erected by Charles V. The outside of the Alcazar is miserable in its appearance, but the first court after entering the gate has a very grand effect; the part looking into that court is purely Arabic in its style, though ascertained to have been constructed since the conquest by the Christians. The courts are ornamented with marble fountains, and are well shaded with corridors, supported by marble pillars. The garden of the Alcazar is said to have been laid out by the Moors, and is preserved in its original state. It contains walks paved with marble, parterres laid out with evergreens, and shaded with orange-trees. In many parts of it there are baths, supplied by marble fountains from an aqueduct, and they have a contrivance for rendering the walks one continued fountain by forcing up small streams of water from minute pipes in the joinings of the slabs, which in this climate produces a most grateful effect. As a specimen of an Arabian garden in its original state, this is an interesting object, and we naturally associate with it recollections gathered from the Eastern writers; especially from the Song of Solomon, in which the descriptions very well agree with this garden; for, in addition to the other circumstances, it is completely walled round, and is secluded from every one, except the inhabitants of one part of the palace. (Jacob’s Travels in the South of Spain.)

292. The remains of a reputed Moorish garden still exists at Grenada, another residence of the Arabian kings. It is situated on the Serra del sol, or mountain of the sun, occupies above twenty acres, is covered with wood cut into quarters by straight and winding walks, and interspersed with fountains; the latter sometimes ostentatiously displayed, and at other times secreted so as to escape notice till they are brought to play on tbe spectator, and raise a laugh at his expense. Sir John Carr mentions that they take a particular delight in playing off these reversed showers which rise from the principal walks and places of repose, against the ladies. Several of these fountains, and many of the walks were formed by Charles V., so that excepting certain venerable cypresses, and the old palace, no other part can with certainty be traced to the days of the Moorish kings.

293. In the beginning of the fifteenth century, soon after the union of Spain under one monarch, Charles V. made considerable improvements, and formed gardens and fountains at different palaces, of which little now remain.

294. In the beginning of the seventeenth century, under the reign of Philip IV. were laid out the finest gardens in Spain. These are the gardens of the Escorial in Madrid, of Ilephonso in its neighbourhood, and of Aranjuez near Toledo. Evelyn in 1667, being anxious to receive some account of them, writes to the Earl of Sandwich, then the English ambassador at Madrid, who answers him in such a way that Evelyn was exceedingly affected with the descriptions, and greatly instructed in many particulars."

The gardens of the Escorial adjoin the palace from which you descend to them by vast terraces and stairs of marble varied by fountains. The garden, or rather park below, is of great extent, and the compartments formed by the intersection of the alleys, are filled with different sorts of fruit-trees. This is the general outline, and for the details of the statues, fountains, trellis-work, basins, &c. we must refer the reader to Thompson’s Description of the Escorial; or the art. Escorial, in the Encyc. Brit.

The garden of Ilephonso is situated around a summer-house, or Chateau de plaisance of that name; and that of the King of Navarre, les jardins de l’Ebre yu Espano, comprise to spread their respective live beauties, and render this garden as magnificent as agreeable. Fountains, jets-d’eau, canals, temples, covered seats, cabinets, bowers, grotoes, labyrinths, pastures, hedges of myrtle and laurel, are so distributed as to produce the best effect. The water is collected in streams from the surrounding mountains, and made to unite in a torrent which precipitates itself into an immense reservoir. Hence, from this abundant source, the fountains are as powerful as numerous, and no species of artificial ornament is omitted that can embellish a garden. The alleys are very long, some of them three fourths of a league. Most of them are kept shorn on the sides forming a thick close surface from the ground to the summits of the trees, and statues are placed at regular distances.

The garden of Ilephonso occupies a ridge, rising to the south, and falling both to the east and to the west. The whole surface is laid out with clipped hedges and straight walks, highly adorned and refreshed with numerous fountains; but in proportion to the distance it becomes more wild, till it terminates in the uncultivated and pathless forest, where the craggy rocks appearing among oaks and pines, present a striking contrast with the works of art. This garden, Townsend observes, is delightful for its walks, which although not extremely beautiful; and if it be true that beauty is founded on utility, this place will always deserve to be admired. In the present day, it is not uncommon to build the mansion in the middle of a field, open and exposed to every wind, without shelter, without a fence, wholly unconnected with the garden. Near it habitations all is wild; and art, if anywhere, appears only at a distance. In all this we can trace no utility, nor will succeeding generations discover beauty. On the contrary in the garden of St. Ilephonso, we find every thing, which in a sultry season is desirable; a free circulation of air, a deep shade, and refreshing vapors to absorb the heat; whilst from its contiguity to the mansion the access to it is easy, and at any time these comforts may be instantly enjoyed; yet without their numerous
fountains, the clipped hedges, and the narrow walks, the circulation would be less rapid, the shade less deep, and the refreshing vapor would be wanting. (Townsend's Travels in Spain, i. 380.)

Of the palace and gardens of Aranjuez, Baretli observes (Tour in 1776, vol. iv.), 'that a poet would say, that Venus and Love had here consulted with Catullus and Petrarch, in order to construct a country-residence worthy ofPsyche, or Elysia, ofLaura, or of some Infanta of Spain.' The park, which is several leagues in circumference, is intersected by alleys, three, and even four miles in length; these alleys are formed of double rows of elms, and are sufficiently wide for four carriages to drive abreast. On each side, between the rows of trees, is a canal kept clear by a continual stream which passes through it. This water has contributed to render the trees of an enormous size and thick verdure from top to bottom. The compartments, or islands, formed by the alleys and the canals, are covered with cypress, and occupied with deer, wild boars, hares, rabbits, pheasants, partridges, and other wild animals and birds, which are regularly fed by certain shepherds or attendants, and have incredibly multiplied. This park, like the garden of Eden, is divided by a river (the Tagus), and what is remarkable and prince-like, it is without surrounding walls, but verges into an open hilly country. The palace is near the centre of the park, on the margin of the river, and both banks are united by a bridge of five arches. In front of the palace is an immense circular lawn, ornamented with four trees in its center, and with the whole, according to Baretli's description, this must have been the finest park in the old style in the world.

295. Of private gardens, a few are mentioned by Townsend, and Sir John Carr, some as belonging to British merchants, and situated round the principal sea-ports, and a few to Spanish nobles in the interior. At the Retiro, near Malaga, a seat of Count Villacasa, and formerly a royal residence, are gardens in the Moorish style, with straight cypress walks, and excellent water-works. The archbishop of Valencia has a country-house and beautiful gardens at Puzol, near the city. The hermitages of Montserrat, near Tarragona, abound in oak, olives, ash, elm, box, myrtle, eglantine, jessamine, rosemary, lavender, thyme, and other aromatic shrubs and plants, tastefully disposed among the rocks and declivities, by the hand of nature, with very little assistance from man.

Granjas, the seat of Don Ramon Fortuny, near Tarragona, appears to be in good taste, combining the ancient style with the cultivation of the orange, fig, vine, olive, and other fruits, and with an accidental mixture of rocks and picturesque scenery. A very interesting engraving of this peculiar and beautiful residence is given by Sir John Carr, in his travels in Spain; the doors of the dining-room, he informs us, open into a small garden, the walls of which are covered with myrtles, jessamines, and roses, and the view is over an orchard of olives, oranges, and pomegranates. In the centre of the garden are grotesque water-works. We are not aware of any attempt to introduce the modern style of landscape-gardening in this country.

296. Gardening in Portugal is very little attended to as an art of taste. Travellers mention a few villas belonging to merchants in the neighbourhood of Lisbon; and, as usual, there are some avenues or public walks near the town. Montserrat, near Cintra, a seat of the late eminent merchant, Beckford, was formed at immense expense by a native of Cornwall for M. de Vismes, and further improved by the former gentleman. It is laid out in the geometric style; abounds in inequalities, stairs, terraces, statues, and orange-trees. Of late, we are informed, it has been much neglected. Repton (Frag. on Lands. Gard. 1815) gives an engraving of a plan which he had sent out to Lisbon, for laying out a small garden in the modern style.

SUBSEC. 2. Spanish and Portuguese Gardening, in respect to the Culture of Flowers and Plants of Ornament.

297. The study of plants is of great antiquity in Spain. This study was introduced by the Arabs; there was a considerable collection of plants at Seville early in the eleventh century; and half the common plants of the country, Harte informs us, have names derived from the Arabic. The succeeding centuries present a blank in this branch of gardening history. According to Deleuze, the taste shown for botany in Spain and Portugal, at the beginning of the sixteenth century, declined with the sciences; and that country where they had been cultivated when the rest of Europe was in a state of barbarism, appeared to sink into apathy, after having shone with the greatest eclat under Charles the Fifth and Emanuel of Portugal.

298. The public garden of Madrid was established in 1753. Ferdinand the Sixth gave its direction to his first physician, Don Joseph Sagnol. He bought the private garden of Don Joseph Queer, who cultivated at home a great number of foreign plants: he named this botanist professor, and added Don Jean Minuart. At the same time, he arranged instructions for travellers going to America, and ordered them to bring home seeds, and to add the indication of the climate, and the nature of the soil where they collected them. They also sent travellers with particular orders to make collections of vegetables. It is from these treasures that the royal garden of Madrid has become the nursery of the plants of Peru, Mexico, and Chili; and from thence they have been sent to other gardens of Europe. The same king, Sir J. E. Smith informs us (Suppt. Encyc. Brit. art. Botany), invited Linnaeus, with the offer of a large pension, to superintend a college formed for the purpose of making new enquiries into the history of nature and the art of agriculture. Linnaeus, as appears by his correspondence, recommended Læfling.

299. A taste for flowers and plants of ornament is not very general in Spain, though odoriferous flowers, as the jessamine, the orange, &c. are said to be in repute with the ladies; and various sorts are grown in the conventual gardens of the priests, for official decorations in churches and oratories.

300. The botanic garden of Coimbra in Portugal was founded in 1773.
301. **Horticulture** has made but little progress in Spain. The earliest of the few Spanish authors who have written on gardens, is Herrera, whose book on rural economy appeared early in the seventeenth century. It contains a treatise on gardens (De las Huertas), in which he distinguishes only two sorts; one for "delight and provision for the house," and the other for supplying the public market. Private gardens, he says, need not be extensive; those for selling vegetables and fruits should be near a town or village, and well supplied with water. He gives directions for cultivating the vine, fig, olive, apple, pear, and the common culinary plants. Of these, the soil and climate are peculiarly favorable to the alliaceous and cucurbitaceous tribes, some sorts of which, as the onion and winter-melon, form articles of foreign commerce.

302. **The fruits of Spain** are more numerous than those of any other European country. Besides all those of Italy, native or acclimated, Spain possesses the date, tamarind, and various fruits of the West Indies. The varieties of the grape, fig, melon, and orange are numerous, and many of them excellent. The pine-apple is little cultivated in Spain; but is grown in a few places, in the southern provinces (Jacob), in the open air.

303. **Culinary herbs and roots** are not much attended to in Spain. Onions and garlic are in universal use; and the sweet potatoe (Convolvulus batatus) is cultivated in various places. The British residents import their potatoes from their native country.

304. **Forcing** is unknown in Spain, but there are hot-houses for plants at Madrid, and at Coimbra and Montserrat in Portugal.

305. **Planting timber-trees or hedges** is scarcely known in either Spain or Portugal.

**Sect. X. Of the Rise, Progress, and present State of Gardening in European Turkey.**

306. Of Turkish gardening, when the country was under the Romans, nothing is known. The Roman taste would pass to Byzantium when the seat of empire was removed there in the fourteenth century by Constantine; but as to its history when the rest of Europe was enveloped in ignorance and superstition, very little is known. The numerous Greek authors on rural matters (Geponici), who wrote between the fourth and fourteenth centuries, do little more than copy Columella and other Latin georgical writers; they mention very few plants as ornamental, and treat chiefly of agriculture, vineyards, and poultry.

307. **The modern taste for gardens** in Turkey is materially influenced by their national character, and the nature of the climate. Gardens of taste are considered places of shade, repose, and luxurious enjoyment; not of active recreation, or a varied display of verdant scenery. "For some miles round Adrianople," Lady M. W. Montague observes, in 1717, "one sees nothing but gardens. The rivers are bordered with fruit-trees, under which the citizens divert themselves in the evenings; not in walking, which is not a Turkish pleasure, but in seating themselves on a carpet spread on the turf, under the thick shade of a tree; there they take coffee, and smoke amidst vocal or instrumental music, groups of dancing females, and other sports."

308. The gardens of the sultan at Constantinople acquired a degree of celebrity through the letters of Lady M. W. Montague, to which, it appears from subsequent authors who have examined them, they are by no means entitled. These gardens were visited by Dr. Pouqueville in 1798, and it is generally allowed that he has described them with as little imagination and as much accuracy as any writer. The grand seignior’s gardener was then a German, a native of Rastadt, by name Jaques, whose salary was 6000 piastres a-year. He conducted Dr. Pouqueville and his companion between the first and second ramparts of the town, which form the natural fortifications of the seraglio on the side to the sea.

The **palace** is, properly speaking, a town within itself, having its walls crowned with battlements, and its bastions and its gates, like an old fortified place. Dr. Clarke says, that the seraglio occupies the whole site of the ancient Byzantium; and Pouqueville, that the present **manege** is placed where there was a hippodrome at the time of the lower empire; so that the destination of the place has not been much altered for the last fifteen hundred years. The first garden they saw was a place enclosed on three sides, with a palisade, the fourth side being formed by the rampart. It was filled with shrubs; such as early roses, heliotropes, and others, distributed in clumps, with several beams, and a great deal of rubbish lying about. At last they arrived at the entrance of the sultan’s garden.

The **gateway to the garden** is of white marble, about fifteen feet high, by four wide, decorated with columns, in a very bad taste. A treillage, twenty-five feet high and fifteen wide, extremely massy, forms a cross, running each way, from one side to the other of the garden, dividing it into four equal divisions. In the centre of the cross, it forms a basin over a small basin of white marble, in which is a jet-d-eau. Jaques ordered some of the men to make it play, but the water did not rise above six feet. It was, indeed, an exhibition much below mediocrity. The four squares formed by this cross, are planted with flowers, and in the middle of each are basins again, with jets-d-eau quite in miniature. That to the left, as we entered, appeased the most singular of them. After the water has risen to the height of about four feet, it divides, like a parasol, and each stream falls upon a shell, upon the circuit of the basin, which again divides it into an innumerable number of still smaller streams, scarcely bigger than threads. We contemplated this chef-d’œuvre for some minutes, and thought it very pretty for amusing children.
The treillage, a work truly German, seems, from its solidity, calculated to brave the injuries of time for a long series of years. It is covered with jessamine, which perfumes the whole garden; and, to say the truth, it has no difficult task to perform, for the enclosure is so small, that there can hardly be said to be sufficient space for the air to circulate freely. To the right, which is the side towards the sea, the treillage leads to the kiosque of the grand seignior, called Jeni-kiosque, the new pavilion. Three circular steps lead up to it, which occupy, in the semicircle they form, the portion of the kiosque that projects into the garden.

A number of cages, with canary-birds, were hanging about; these little creatures sung charmingly, and had been taught to draw water. About fifteen paces from this kiosque, running along the same rampart, is a terrace of about fifty feet in length, and twelve in breadth, adorned with flowers, which has lately been turned into a conservatory.

The largest garden, to which they descended from the terrace, is a hundred and twenty paces long, and fifty broad. At the eastern extremity is a hot-house, where Jacques was cultivating a number of foreign plants and flowers with great care. The hot-house was little better than a shed; under it were a number of benches, rising in a stage one above the other, with the flower-pots ranged upon them. Among the plants, some from Abyssinia and the Cape held a distinguished rank for their superior fragrance. Another garden, or rather a terrace, raised five-and-twenty feet high, which looks down upon the garden just quitted, contained nothing but a red and parched soil, with a few withered plants.

An aviary had been made by order of the Sultana Valide; and this, according to the ideas of the Turks, is the most curious thing upon the terrace. "I quitted this dismal garden," says Dr. Pouqueville, "this kiosque of Hassan Pasha, perfectly free from the chimeras with which my imagination had been previously filled. I had formerly read the letters of Lady Montague, and I seriously believed that I was to find walls incrusted with emeralds and sapphires; parterres enameled with flowers; in short, the voluptuous palace of Armida; but her account is drawn from the sources furnished by her own brilliant imagination."—We quitted the burning garden to visit the harem. The harem of the sultan—the promised paradise. Lady Montague was now about to triumph.

The garden of the harem is a square very ill kept; it is divided from east to west by a terrace. It was here that the feast of tulips was formerly held; but this has been long abolished. According to all appearance it must have been a very poor thing; but the pens of romance-writers can embellish objects the most ordinary, and make them appear of prodigious importance. Some clumps of ilacs and jessamine, some weeping willows hanging over a basin, and some silk-trees, are the only ornaments of this imaginary Eden; and these the women take a pleasure in destroying as soon as the flowers appear, by which their curiosity is excited.

A plan of these gardens is given by Krafft (fig. 27.), from which little can be gathered but that they abound in trees and buildings, and are surrounded by a formidable wall.
been led to entertain of the luxury and magnificence that reigns in the grand seignior's seraglio. (Pouqueville's Travels, translated by H. M. Williams.)

310. Flower-gardening. "When the Turks," observes Deleuze, "by the taking of Constantinople, had given stability to their empire, they devoted themselves particularly to the culture of flowers." Belon, in 1558, speaks with admiration of the gardens which he saw among them. "There are no people," he says, "who delight more to ornament themselves with beautiful flowers, nor who praise them more, than the Turks. They think little of their smell, but delight most in their appearance. They wear several sorts singly in the folds of their turban; and the artisans have often several flowers of different colors before them, in vessels of water. Hence gardening is in as great repute with them as with us; and they grudge no expense in procuring foreign trees and plants, especially such as have fine flowers." Busby, ambassador at Constantinople in 1550, has the same remarks, and adds, that they frequently give flowers in presents; and that, though very avaricious in other things, they do not hesitate to pay dear for them.

311. Of the horticulture of Turkey little is known, or how far the use of gardens is general. "The capital of the Turkish empire," T. Thornton observes (Present State of Turkey, 22.), "though the soil in its immediate vicinity is barren and ungrateful, receives from the neighbouring villages, and from the surrounding coasts of both the seas which it commands, all the culinary herbs and fruits of exquisite flavor which the most fastidious appetite can require. On the shores on both sides of the Bosphorus the ground forms a chain of schistous hills, covered with vineyards and gardens, and beautiful trees and shrubs; and the valleys, which are exceedingly fertile, are in the highest state of cultivation."

Of the botany and gardening of the Morea some account is given by Dr. Pouqueville. (Travels in 1798.) "This country, formerly a part of Greece, is rich in vegetable productions, but at present proportionably poor in cultivation. There is no great variety cultivated in the gardens; the ground in general is ill prepared; the Greeks are unacquainted with the spade, and only use a mattock for turning it. Spinach and artichokes, which will even grow naturally without cultivation, are among the best culinary vegetables. Cabbages and cauliflowers grow to a prodigious size; they have also very good carrots. Beans and French beans are produced in such abundance, that they might become an object of exportation; but the seeds of both are much smaller than ours in France. The lettuces are small; and the celery never will be good while, as at present, they do not earth it up. The tomatoes are very fine, as is the fruit yielded by the melonoga. The melons, water-melons, and gourds, are not to be exceeded in any part of the world. Mint, balm, fennel, parsley, and other herbs, abound in the gardens. The orchards are well furnished with almonds, oranges, lemons, cinetons, peaches, pears, apricots, quinces, cherries, pomegranates, medlars; they have also the arbutus, the service-tree, and the carob-tree; all these might be improved, if more pains were taken in cultivating them." (p. 204.) The account which this author, and also Dr. Holland (Albania and Greece, &c. 1812 and 1815), gives of the plants, the timber, and the fruit-trees, natives of the Morea, is highly interesting; he regrets that he could not occupy himself more with the subject, adding, that a botanist might compose a work worthy of the age in which we live, in undertaking a complete Flora Peloponnesica.

Chap. IV.

Of the Rise, Progress, and present State of Gardening in the British Isles.

312. That gardening was introduced to Britain by the Romans, there can be but little doubt. According to Strabo, writing in the fourth century, "The people of Britain are generally ignorant of the art of cultivating gardens, as well as of other parts of agriculture" (lib. iii. p. 200.); but Tacitus, half a century afterwards (A. D. 79), informs us, that "the soil and climate were very fit for all kinds of fruit-trees, except the vine and the olive; and for all plants and edible vegetables, except a few, which were peculiar to hotter countries." (Vita Agric. cap. xiv.) Afterwards they found different parts of the country not unfit for the vine; and wine was made in England towards the end of the third century, under the Emperor Probus. The remains of Roman villas discovered in different parts of the country may be considered as existing evidence that Roman gardening was established, both as an art of taste, and of vegetable culture, by the generals and other members of the government. Pliny expressly states, that cherries were introduced into Britain about the middle of the first century: they had been brought to Italy by Lucullus only a century before.

313. Modern British gardening seems to have received its first stimulus during the reign of Henry VIII.; a second powerful impulse in the time of Charles II., with the splendid style of Le Notre; again, with the introduction of the modern style during the reign of Geo. II.; next, in the early part of the reign of Geo. III. with the plants of North America, and finally through the establishment of the Horticultural Society during the regency.

314. The outline of gardening history here submitted will be found amply illustrated by the literature and topography of British gardening in Part IV., and indeed by all the other chapters on the statistics of British gardening.
GARDENING IN THE BRITISH ISLES.

Sect. I. British Gardening as an Art of Design and Taste.

315. Of British gardening, as an art of taste, nothing is known for the first thousand years of our era. With the eleventh century commences some notices as to England; with the fifteenth, a few indications as to Scotland; and with the seventeenth century, some hints as to the state of our art in Ireland.

316. Roman landscape-gardening was lost in England when that people abandoned Britain to the Saxons in the beginning of the fifth century; but as it had revivified in France under Charlemaigne, it would probably be re-introduced into England with the Norman Conqueror, in the end of the eleventh century.

317. Henry I. (1100), the third king after William the Conqueror, had, according to Henry of Huntingdon (History, lib. 7.), a park (habitationem ferarum) at Woodstock; and it may not be too much to conjecture, that this park was the same which had surrounded the magnificent Roman villa, whose extensive ruins, occupying nearly six acres, have been recently dug up on the Duke of Marlborough's estates in that neighbourhood. Blenheim, the first residence in Britain, or perhaps in Europe, in respect to general grandeur, may in this view be considered as the most interesting in point of its relation to antiquity.

318. In the time of Henry II. (1154), Fitzstephen, it is observed by Daines Barrington, states, that the citizens of London had gardens to their villas, "large, beautiful, and planted with trees." In De Cerceau's Architecture, published in the time of Henry III., there is scarcely a ground-plan not laid out as a parterre or a labyrinth.

319. During Henry V.'s reign, in the beginning of the fifteenth century, King James I. of Scotland was a prisoner in Windsor castle for several years. In the poem written by that monarch he gives the following account of a royal garden there:—

"Now was there maidie fast by the tours wall
A garden faire, and in the corners set
Ane herbere green, with wandis long and small
Raitit about, and so with trees set
Was all the place, and hawthorn hedges knet,
That lyfe was non, walking there for byre
That myght within scarce any wight espie.

So thich the bewis and the leves grene
Beschuidit all the alleys that there were,
And myddis every herbere might be sene
The sharp grene swete jenepere,
Growing so fair with branches here and there,
That as it semyt to a lyfe without
The bewis spred the herbere all about."

The Quair, by King James I. of Scotland, published by Lord Woodhouselee.

320. Towards the end of the fifteenth century, Leland, in his Itinerary, states, that at "Wresheill Castelle, in Yorkshire, the gardeins within the mote, and the orchardes without, were exceeding fair. And yn the orchardes, were mountes, opere topiaris, written about with degrees like cokil shelles, to com to the top without payn." (Itinerary, &c. p. 60.) Such a mount still exists at the castle inn at Marlborough, not ascended by steps or degrees, but by a winding path. It is covered with ancient yew-trees, no longer opere topiaris. Leland also mentions the gardens at Morli, in Derbyshire, and some others of less note in the northern counties.

321. During the reign of Henry VII., Holingshead informs us, that large parks or circumscribed forests of several miles in circumference were common. Their number in Kent and Essex alone amounted to upwards of a hundred. (p. 304.) The Earl of Northumberland had in Northumberland, Cumberland, and Yorkshire, twenty-one parks, and 5771 head of red and fallow deer. He had also parks in Sussex, and other southern counties. These parks were formed more from necessity than luxury; tenants for land being then not so readily obtained as in later times.

322. During the reign of Henry VIII. the royal gardens of Nonsuch were laid out and planted. "At Nonsuch," says Hentzner, "there were groves ornamented with trellis-work, cabinets of verdure, and walks embowered with trees, with columns and pyramids of marble. Two fountains that do spout water, the one round the other like a pyramid, on which are perched all over, small birds that spout water out of their bills." These gardens are stated, in a survey taken in the year 1650, above a century after Henry's death, to have been cut and divided into several alleys, compartments, and rounds, set about with thorn-hedges. On the north side was a kitchen-garden, very commodious, and surrounded with a wall fourteen feet high. On the west was a wilderness severed from the little park by a hedge, the whole containing ten acres. In the privy-gardens were pyramids, fountains, and basins of marble, one of which is "set round with six lilac-trees, which trees bear no fruit, but only a very pleasant smell." In the privy-gardens were, besides the lilacs, 144 fruit-trees, two yews, and one juniper. In the kitchen-garden were seventy-two fruit-trees and one lime-tree. Lastly, before the palace, was a neat handsome bowling-green, surrounded with a balustrade of freestone. "In this garden," observes Daines Barrington, "we find many such ornaments of old English gardening, as prevailed till the modern taste was introduced by Kent."
Hampton-court was laid out about the middle of this reign, by Cardinal Wolsey. The labyrinth, one of the best which remains in England, occupies only a quarter of an acre, and contains nearly half a mile of winding walks. There is an adjacent stand, on which the gardener places himself, to extricate the adventurous stranger by his directions. Switzer condemns this labyrinth for having only four stops, and gives a plan for one with twenty. Daines Barrington says (ArcaeoLog.), that he got out by keeping close to the hedge.

333. During Elizabeth's reign, Hatfield, Lord Treasurer Burleigh's, Holland-house, and some other old seats were laid out. Of Hatfield, Hentzner says, the "gardens are surrounded by a piece of water, with boats rowing through alleys of well cut trees, and labyrinths made with great labor; there are jets-d'eau and a summer-house, with many pleasant and fair fish-ponds. Statues were very abundant. The Gardener's Labyrinth, published during this reign, contains plates of "knotts and mazes cunningly handled for the beautifying of gardens."

324. During the reign of James I. the gardens of the Theobalds and Greenwich were formed or improved. The garden at Theobalds, Mandelso, a traveller who visited England about 1640, describes as "a large square, having all its walls covered with filerry (trellis-work), and a beautiful jet-d'eau in the centre. The parterre hath many pleasant walks, part of which are planted on the sides with espaliers, and others arched over. Some of the trees are limes and elms, and at the end is a small mount, called the Mount of Venus, which is placed in the midst of a labyrinth, and is upon the whole one of the most beautiful spots in the world." (Voyages de Mandelso, tom. i. p. 598.) Lord Bacon attempted to reform the national taste during this reign, but apparently with little immediate success. He wished still to retain shrorn trees and hedges; but proposed winter, or evergreen gardens, and rude or neglected spots, as specimens of wild nature. "As for the making of knots or figures," says he, "with divers colored earths - they be but toys. I do not like images cut out in juniper or other garden-stuff - they are for children." (Essay on Gardens.) Sir Henry Wotton says, "the garden at Lord Verulam's was one of the best he had seen, either at home or abroad." Lawson's New Orchard was published in 1626; he gives directions also for parterres and labyrinths. A curious idea is given of the taste of these times in what he says of the latter. "Mazes well framed a man's height may, perhaps, make your friend wander in gathering berries, till he cannot recover himself without your help."

325. During the commonwealth a Janua Trilinguis was published at Oxford, in which we are informed, that "gardening is practised for food's sake in a kitchen-garden and orchard, or for pleasure's sake in a green grass-plot and an arbor." As to the formation of the latter, the author adds, "the pleacher (topiarium) prepares a green plat of the more choice flowers and rarer plants, and adorns the garden with pleach-work; that is, with pleasant walks and bowers, &c. to conclude with purling fountains, and water-works." (chap. 32.) We learn also from this comprehensive author (Commenius) the ancient use of parks. "We are told," he says, "the huntsman hunteh wild beasts, whilst he either allureth them into pitsalls, and killeth them, or forceth them into toils; and what he gets alive he puts into a park." (chap. 87.)

326. During the reign of Charles II., landscape-gardening received a grand impulse. This monarch, we are informed by Daines Barrington, sent for Perault and Le Notre; the former declined coming to England, but the latter planted Greenwich and St. James's Parks. Charles planted the semicircle of Hampton Court; the beginning, as Switzer informs us, of a grand design never completed. Lord Capel and the Earl of Essex are mentioned by Switzer as eminent encouragers of gardening during this reign. The latter sent his gardener, Rose, to study the most celebrated beauties of Versailles; and on his return he was appointed royal gardener.

Chatworth (fig. 28), the magnificent seat of the Duke of Devonshire, was laid out in this reign; and it is conjectured, from a design from the same artist. (Beauties of England and Wales. Derbyshire.) Waller the poet formed his residence at Beaconsfield about the same time. The grounds there being very irregular, he has been at considerable labor in reducing the parts near the house and banqueting-room to regular figures, harmonising basin or canal. It is but an oblong piece of land belonging to this amateur, who was undoubtedly a man of taste in his day, that, in the more remote scenes, no appearance of art is discernible, or seems ever to have been intended. Their dry, ragged-edged paths, conducted through the natural woods, form a fine contrast to the artificial scenes at Prior's Park.

Garden-buildings, Daines Barrington conjectures, were first erected in England during this reign by Inigo Jones, at Beckett near Farringdon. There a banqueting-room is placed on a point of land projecting into a lake, and is surrounded with a broad base, or platform, protected by a parapet-wall, and shaded on all sides by projecting caves of the buildings. It consists of one apartment with a cellar below; and the covered platform, or base, is supposed to be for the purpose of angling.

327. Evelyn, the well-known author of Sylva and other gardening books, flourished during this reign. In his memoirs (published by Bray, 1818) are the following remarks on the gardens of England, in respect to taste and style: —

Wotton, in Surrey, 1632, the residence of his father he describes as, for woods and waters, among the most natural and magnificent examples which England afforded "till this late and universal luxury of the whole nation since abounding in such expenses." —

"Gave my brother some directions about his garden, which he was desirous to put into some form, for which he was to remove a mountain overgrown with large trees and thickets, and a moat within ten
yards of the house: "this his brother "succeeded in doing, by digging down the mountain, and flinging it into a rapid stream, which carried away the sand, filled up the moat, and levelled that noble area where now the garden and fountain is."

Groom's-bridge near Tunbridge, "a pretty melancholy place."

1654. Lady Brook's garden at Hackney, "one of the neatest and most celebrated in England."

Caversham, Lord Craven's, Berkshire. "Goodly woods felling by rebels."

Cashiobury (Fig. 28), Lord Essex, Hertfordshire. "No man has been more industrious than this noble
lord (Essex) in planting about his seat, adorned with walks, ponds, and other rural elegancies." — "The gardens are very rare, and cannot be otherwise, having so skilful an artist to govern them as Cooke, who is, as to the mechanical part, not ignorant in mathematics, and pretends to astrology. There is an excellent collection of the choicest fruit... My lord not illiterate beyond the rate of most noblemen of this age."

Wilton, Lord Pembroke's, Wilts. — "The garden, heretofore esteemed the noblest in England, is a large handsome plain, with a grotto and water-works, which might be made much more pleasant were the river that passes through cleansed and raised; for all is effected by mere force," &c.

Hampton Park, Middlesex. — "For many a flat, naked piece of ground, now planted with sweet rows of lime-trees, and the canal for water now near perfected; also the hare-park. In the garden is a rich and noble fountain, with syrens, statues, &c. cast in copper by Fanelli, but no plenty of water. The cradle-walk of holly-hocks in the garden is, for the perplexed twining of the trees, very observable. There is a parterre which they call Paradise, in which is a pretty banquetting-house set over a cave or cellar."

1662. A Citizen's garden. — "One Loader, an anchorsmith in Greenwich, grew so rich as to build a house in the street, with gardens, orangeries, canals, and other magnificence, on a lease. His father was of the same trade, and an anabaptist." Bushnell's Wells at Enstone. — "This Bushnell had been secretary to Lord Verulam. It is an extraordinary solitude. There he had two mummies, and a grot, where he lay in a hammock like an Indian. Here he built a house, the design of which was to be his seat, an ancient seat of the Lees," &c. — Bushnell's gardens and water-works still exist, and are shown as curiosities to strangers.

Ham House, and garden of the Duke of Lauderdale, Middlesex. — "Inferior to few of the best villages of Italy itself, the house furnished like a great prince's; the parterres, flower-gardens, orangeries, groves, avenues, courts, statues, perspectives, fountains, aviaries, and all this at the banks of the sweetest river in the world, must needs be admirable."

Wanted House, Essex, (fig. 30.) — "Sir Josiah Child's prodigous cost in planting walnut-trees about his seat, and making fish-ponds some miles in circuit in Epping-forest, in a barren spot, as oftentimes these..."

suddenly monied men for the most part seat themselves." — In 1622 this magnificent seat was reduced to a mere mass of materials, through the improvidence of Wellesley Long Pole, who became possessed of it by marriage. The house was sold in lots, and the ground let in small portions on building leases.

Sir Henry Capell's orangery and magnificence at Ken, "most beautiful and perfectly well kept. He was contriving very high palisadoes of reeds to shade his oranges during the summer, and painting these reeds in oil."

Althorp, Lord Northampton's, Northamptonshire. — "The iron gate opening into the park of very good work, wrought in flowers, painted in blue, and gilded." Beddington, the seat of the Carews, Surrey, now decaying, "herefore adorned with ample gardens, and the first orange-trees that had been seen in England, planted in the open ground, and secured in winter only by a tabernacle of boards and stoves, &c. standing a hundred and twenty years. Large and goodly trees, and laden with fruit, now in decay, as well as the grotto and fountains. The cabinets and other curiosities in the house and abroad being now fallen to a child under age, and only kept by a servant or two from further dilapidation. The estate and park about it also in decay."

Marlow, in Buckinghamshire. — "Originally a hunting seat, bought by Sir Robert Clayton, who built there a pretty house, and made such alteration by planting, not only an infinite store of the best fruit, but so changed the natural situation of the hills, valleys, and solitary mountains about it, that it rather represented some foreign country which could produce spontaneously pines, firs, cypress, yew, holly, and juniper; they were come to their perfect growth, with walks, &c. among them." Almorie Howards, Surrey. — "Found the garden exactly done to the design and plot I had made, with the crypt through the mountain in the park, 30 perches in length. Such a Fausalippe [alluding to the grot of Palladino at Naples] is no where in England. The canal was now digging, and the vineyard planted." — This crypt was in part remaining in 1816, but stopped up at the further end.

Swallowfield, Lady Clarendon, Berkshire. — "Lady C. skilled in the flowery part, my lord in diligence of planting. Water flagged with calamus, all that can render a country-seat delightful, and a well furnished library in the house." (Mem. by Britt, l. 422.)

928. During the same reign (Charles II.) notes were made on some of the gardens round London by J. Gibson, which have been subsequently published in the Archæologia. (vol. xii.) Many of those mentioned by Evelyn are included, and spoken of in nearly the same terms by Gibson. Terrace-walks, hedges of evergreens, shrub bushes in boxes, and orange and myrtle trees are mentioned as their chief excellencies. The parterre at Hampton Court is said to resemble a set of lace patterns. Evelyn himself is said to have a "pleasant
vill at Deptford, a fine garden for walks and hedges, and a pretty little green-house with an indifferent stock in it. He has four large round philaraen, smooth-clipped, raised on a single stalk from the ground, a fashion now much used. "Part of his garden is very woody and shady for walking; but not being walled, he has little of the best fruits."  

329. During the reign of William and Mary, gardening, Switzer says, arrived at its highest perfection. King William, Daines Barrington informs us, gave vogue to clipt yeaws, with magnificent gates and rails of iron, not unfrequent in Holland, and about this time (see Huetiana) introduced into France, and, in reference to the opaque stone-walls which they supplanted, called there clairs-roysés. The most extensive iron screens of this sort in England, next to those of Hampton Court, were formed by Switzer, at Leeswold, in Flintshire, laid out by that artist in a mixed style, or what is called Bridgeman's first manner. Hampton Court being at this time the actual residence of the royal family, the gardens underwent considerable improvement. An elegant alcove and arched trellis were added at the end of one of the alleys, and four urns placed before the principal part of the house, supposed by Daines Barrington (Archaeologia) to be the first that were thus used in England. Towards the end of this century, vegetable sculptures, and embroidered parterres, were probably in their highest vogue, a conjecture confirmed by the works of Le Blond, James, Switzer, &c. published during this and the following reign. Sir William Temple's Essay on the Gardens of Epicurus appeared about the same time. His picture of a perfect garden, is that of a flat, or gentle declivity of an oblong shape, lying in front of the house, with a descent of steps from a terrace, extending the whole length of the house. This enclosure is to be cultivated as a kitchen-garden and orchard. Such a garden he found at Moor Park, Hertfordshire, laid out by the Countess of Bedford, celebrated by Dr. Donne, "the sweetest place, I think, that I have seen in my life, before or since, at home or abroad." Lord Walpole, in his enthusiasm for the modern style, observes on this description, that any man might form as sweet a garden, who had never been out of Holborn. — It has long since been destroyed, and its place occupied by lawn and trees.  

330. During Queen Anne's reign, the principal alteration mentioned by Daines Barrington, as having taken place in the royal gardens, was that of covering the parterre before the great terrace at Windsor with turf. Switzer mentions, that her Majesty finished the old gardens at Kensington, begun by King William. Wise, who had been apprentice to Rose, and succeeded him as royal gardener, turned the gravel-pits into a shrubbery, with winding walks, with which Addison was so struck, that he compares him to an epic poet, and these improved pits as episodes to the general effect of the garden. Wise and London afterwards turned nurserymen, and designers of gardens, in which last capacity they were nearly in as great demand as was afterwards the celebrated Brown. To London and Wise, as designers, succeeded Bridgeman, who appears to have been a more chaste artist than any of his predecessors. He banished vegetable sculpture, and introduced wild scenes and cultivated fields in Richmond park; but he still clipt his alleys, though he left to their natural growth the central parts of the masses through which they were pierced. Blenheim, Castle Howard, Cranbourne, Bushy Park, Edger, Althorpe, New Park, Bowden, Hackwood, Wrest, and indeed almost all the principal noblemen's seats in the ancient style, were laid out during this, the preceding, and part of the latter reigns, or between the years 1660 and 1713. Blenheim was laid out by Wise in three years; Wansted and Edger were the last of London's designs. (Switzer.)  

331. During the reign of George I. nothing of consequence appears to have been done to the royal gardens; though, near the end of it, Vanbrugh was appointed surveyor of the waters and gardens of the crown, but continued only a year or two in office.  

332. During the reign of George II. Queen Caroline enlarged and planted Kensington Gardens, and formed what is now called the Serpentine River, by uniting a string of detached ponds. This was a bold step, and led the way to subsequent changes of taste. Lord Bathurst informed Daines Barrington, that he was the first who deviated from the straight line in pieces of made water, by following the natural lines of a valley, in widening a brook at Ryskins, near Colebrook; and that Lord Strafford thinking that it was done from poverty or economy, asked him to own fairly, how little more it would have cost him to have made it straight. From Lord Walpole's correspondence (published 1819) we learn that Queen Caroline proposed to shut up St. James's Park, and convert it into a noble garden for the palace of that name. When her Majesty asked Lord Walpole's father what it might probably cost, he answered "only three crowns."  

Canons, the magnificent seat of the Duke of Chandos, is one of the principal places laid out in the ancient style during this reign. We are ignorant of the name of the French artist who gave the design, but the execution was superintended by Dr. Blackwell, a physician and agriculturist of some note. The Duke is mentioned by Miller, as one of the principal encouragers of gardening. As far as we have been able to learn, the last extensive residence laid out in the ancient style, in England, was Exton Park, in Rutlandshire, then the property of the Earl of Gainsborough, the Macenas of his age. It was finished about the year 1720. Kent had already returned from Italy, and been employed as a painter and architect, and he began to display his genius a few years afterwards as a landscape-gardener.
334. The modern style of landscape-gardening was introduced during the early part of the eighteenth century. The origin of this style, and by whom and where it was first exhibited, have given rise to much discussion, and various opinions and assertions.

The continental nations in general assert that we borrowed it from the Chinese; or with Gabriel Thouin and Malacarne, deny us the merit of being the first either to borrow or invent it, by presenting claims of originality (106. and 78.) for their respective countries. Gabriel Thouin asserts (Planis Itinerales, preface, &c.) that the first example was given by Dufresnoy (106.), a Parisian architect, in the Faubourg Saint Antoine, in the beginning of the eighteenth century. The claims of Malacarne of Padua, in behalf of Charles I. Duke of Savoy, about the end of the sixteenth century, have been already adverted to. In as far as France is concerned, we think that Tasso's claim to priority is indisputable. (See Dissertazione su i Giardini Inglese, by Hippolito Pindelemento, Verona, 1817, or a translation of part of it by us in the New Monthly Magazine, Feb. 1820.) Deleuze, the historian of botany and ornamental plants, (Annales du Muséum, 1823), endeavours to prove that that new style of gardening was the result of the necessity of finding room for the great number of ornamental shrubs and trees introduced from America, during the first half of the eighteenth century. Bettinger, in his Raccoltezonzom zur Gartendkunst der Alter, &c. carries us back to the descriptions of the grotto of Calypso by Homer, the vale of Tempe by Allian, and of Vaucluse by Petrarch.

335. British authors are of various opinions as to the origin of the modern style.

The poet Gray (Life and Letters, &c. Letter to Mr. Hove, dated 1765) is of opinion, that "our skill in gardening, or rather, in getting out the spot, is the only taste we can call our own; the only proof of original talent in matters of pleasure. This is no small honor to us; since neither France nor Italy have ever had the least notion of it."

Warton and Lord Walpole, the former in his Essay on Pope, and the latter in his History of Modern Gardening, agree in referring the first taste of it to Milton; and Warton adds, that the Seasons of Thomson may have had a very considerable influence.

George Mason, the author of an Essay on Design in Gardening, which appeared in 1768, is one of the earliest prose writers on the modern style, states, that "were it only classical authorities on which the modern taste had hitherto depended, any considerable improvement in the art, as it now stands, would have been impossible." (Essay on Design, &c. p. 27.) Speaking of the Chinese style he says, "little did Sir William Temple imagine, that in not much more than half a century, the Chinese would become the nominal taste of his country; ... he did not know that his observation, so prudently made, would become the parents of the modern style of gardening." (Essay on Design, &c. p. 50.) Mason argues, that "the modern improvements in gardening may chiefly be attributed" (Essay on Design, &c. p. 50.) to no man could be a more enthusiastic admirer of the classics, a warmer patriot, or a more rigid critic, than this author; and it appears from another part of his work (Dissertation on Ken, p. 105.) that he was well aware, when he wrote the above passage, that the origin of the modern style was generally traced to Kent. That he should derive it from our attempt at the Chinese manner, we consider as a proof of canard and impropriety.

Mason the poet states, in a note to the English Gardens, that "Bacon was the prophet, Milton the herald, of modern gardening; and Addison, Pope, and Kent, the champions of true taste." The efficacy of Bacon's ideas, G. Mason considers to have been the "introduction of classical landscapes," though this did not appear from his day, the object of which seems to be, to banish certain littlenesses and puerilities, and to create more variety, by introducing enclosures of wild scenery, as well as of cultivation. The title of champion, applied to Addison, alludes to his excellent paper in the Spectator, No. 414. "On the causes of the pleasures of the imagination arising from the works of nature, and the superiority over those of art," published in 1712; and when applied to Pope, it refers to his celebrated Guardian, No. 175. published the following year. Betttinger, however, affirms that the bishop of Arranches had thrown out similar ideas, previously to the appearance of the Spectator. (See Huétana, Penéé 51. Beautés naturelles préférables aux beaux de la mode.)"

The Rev. Dr. Alison, author of the Analysis of Beauty, seems to consider the modern style as derived from our taste for the classic descriptions of the poets of antiquity. "In this view," (alluding to the progress of art from the expression of design to the expression of variety and natural beauty,) he adds, "I cannot but think that the modern taste in gardening (or what Mr. Walpole very justly and very emphatically, calls the art of creating landscape,) owes its origin to two circumstances, which may, at first, appear paradoxical, viz. to the accidental circumstances of our taste in natural beauty being founded upon foreign models; and to the different circumstances of the scenery of our own country to that which we were accustomed peculiarly to admire."

Eustace, the Italian tourist, considers Tasso's garden of Armida as more likely to have given rise to the English style than any classical work, or even the Paradise of Milton.

Our own opinion coincides with that of Alison, with but one exception, that examples of wild scenery, with walks, may have been exhibited long before both in Italy and this country. The general progress of ideas in matters of taste and refinement, required the creation of such a style; and the highly-cultivated state of the country, the accounts of Chinese gardens, and the descriptions of the poets, would all conspire to its production.

336. The principles of modern landscape-gardening were unquestionably first laid down by English writers. It is allowed on all sides, that Addison and Pope "prepared for the new art of gardening the firm basis of philosophical principles." Addison's paper on Imagination, was published so early as 1712; and Pope's celebrated Guardian on Verdant Sculpture, in 1713. Pope attacked the verdant sculpture, and formal groves of the ancient style, with the keenest shafts of ridicule; and in his epistle to Lord Burlington, laid down the justest principles of art; the study of nature, of the genius of the place, and never to lose sight of good sense.
337. The first examples of modern landscape-gardening were given by Pope and Addison. In so far as was practicable on a spot of little more than two acres, Pope practised what he wrote; and his well-known garden at Twickenham contained, so early as 1716, some highly picturesque and natural-like scenery; accurately described by various contemporary writers. Only the soil of Pope’s garden now remains. (See Beauties of England and Wales.) Addison had a small retirement at Bilton, near Rugby, laid out in what may be called a rural style, and which still exists, with very little alteration besides that of time.

338. The first artists who practised in the modern style, were Bridgeman and Kent. Bridgeman was the fashionable designer of gardens in the beginning of the 18th century, and may be considered as having succeeded to London and Wise, London having died in 1713. Lord Walpole conjectures Bridgeman to have been “struck and reformed” by the Guardian, No. 173. He banished verdant sculpture, and introduced morsels of a forest appearance in the gardens at Richmond; “but not till other innovators had broke loose from rigid symmetry.” But it was reserved for Kent, the friend of Lord Burlington, says Daines Barrington, to carry Pope’s ideas more extensively into execution. It was reserved for him “to realise the beautiful descriptions of the poets, for which he was peculiarly adapted by being a painter; as the true test of perfection in modern gardening is, that a landscape-painter would choose it for a composition.” Kent, according to Lord Walpole, appeared immediately after Bridgeman began to make innovations on the old style. Among these innovations the capital stroke was the destruction of walls for boundaries, and the introduction of ha-has;—the harmony of the lawn with the park followed. Kent appeared at this moment, and saw that all nature was a garden; “painter enough to taste the charms of landscape, bold and opinionative enough to dare and to dictate, and born with a genius to strike out a great system; from the twilight of imperfect essays, he realised the compositions of the greatest masters in painting.” “Kent,” continues his lordship, “was neither without assistance nor without faults. Pope contributed to form his taste; and the gardens at Carleton House were probably borrowed from the poet’s at Twickenham.”

339. The origin and establishment of the modern style of landscape-gardening in England appears thus to have been effected by Addison, Pope, Bridgeman, and Kent.

The various deviations from rigid uniformity, or more correctly, the various attempts to succeed in the Chinese manner, appear to have taken a new and decisive character under the guidance of Kent, a circumstance, in our opinion, entirely owing to his having the ideas of a painter; for no mere gardener, occupied in his small plot, would ever have dared, or even have attempted pictoresque effect. Picturesque beauty, indeed, we consider to have been but little recognised in this country, excepting by painters, previously to the time of Pope, who was both a painter and a poet. The continued approbation of the modern style, as purified from the Chinese absurdities, originally more or less introduced with it, and continued in many places long after Kent’s time, we consider to be chiefly owing to the circumstance of the study of drawing and landscape-painting having become a part of the general system of education; and thus, as Alison observes, our taste for natural beauty was awakened; “the power of simulating nature, the removal of artificial bounds, and the removal of the articles of acquired expression, led men only more strongly to attend to the natural expression of scenery, and to study the means by which it might be maintained or improved.”

340. The adoption and extension of the modern style in England may next be considered. The means which led to its popularity in Britain, and indeed over the whole of Europe, were the examples of artists and authors, to which it gave rise.

341. The country-seats in which the modern style was first employed are described by Shenstone, G. Mason, and Wheatley, in their works on gardening, and incidentally by some other authors.

Stowe appears to have been the first extensive residence in which the modern style was adopted. Lord Cobham seems to have been occupied in re-modelling the grounds at Stowe, about the same time that Pope was laying out his gardens at Twickenham. His lordship began these improvements in 1714, employing Bridgeman, whose plans and views for altering old Stowe from the most rigid character of the ancient style to a more open and irregular design, are still in existence. Kent was employed a few years afterwards, first to paint the hall, and afterwards in the double capacity of architect and landscape-gardener; and the finest buildings and scenes there are in creation. The character of Stowe is well known; nature has done little; but art has created a number of magnificent buildings, by which it has been attempted to give a sort of emblematic character to scenes of little or no natural expression. The result is unique; but more, as expressed by Pope, “a work to wonder at,” than one to charm the imagination. Thus we do not consider him as the first man who exhibited to his country, if we may judge from the concluding lines of an epitaph to his memory, placed in the garden.—

ET ELEGANTISSIMI HORTORUM CULTU PRIMUM IN AGROS ILLUSTRATO PATRIAM ORNAVIT, 1747.

Windsor, the splendid residence of Bridgeman, is supposed to have been one of the first small places where the new system struck out by Kent was adopted. Southcote, says G. Mason, possessed a genius in many respects well suited to the purpose, but was rather too lavish of his flowery decorations. The extent of the grounds was one hundred and fifty acres, thirty-five of which were ornamented to the highest degree, the whole covered with remaining woods, and the rest in tillage. The decorations consisted in having a broad margin of shrubbery and gravel-walk to almost every fence, but varied by difference of style, views, buildings, &c. It is minutely described in Wheatley’s Observations, as it was intended for men of fashion. Mason thinks the fancy of the strip of narrow, and sometimes offensive, from the impossibility of concealing the fence. To this bordering walk, he thinks it may probably be attributed the introduction of the belt. His remarks refer to the year 1768. In 1803, it had repeatedly changed proprietors, and scarcely a vestige remained to distinguish it from a common farm.

Pains Hill, the creation of the Hon. Charles Hamilton, ninth son of James, sixth earl of Abercorn, is supposed to have been one of the next specimens exhibited of the modern style. Hamilton is said to have studied pictures, with a view to the improvement of grounds. Pains Hill is a small park, surrounded on
three sides by garden and picturesquely scenary. Excepting from the house, there is no distant prospect; but the surface being considerably undulated, the views from the walks across the park have some variety, and are always agreeable. This place is one of the few, described by Wheatley, which is still in perfect preservation.

Hagley seems to have been improved about the same time as Pains Hill, in effecting which, Lord Lyttelton might probably receive some hints from the poet Thomson, who was then his guest. The grounds are much varied, and the distant prospects picturesquely. A very small rill, which passed through the grounds in a sort of dell, was surrounded with shrubs and yews, from which the park-scenery formed a beautiful foreground; thus, in the middle distance to the offscapes, in the centre of the park, "blending the excellencies of the park and the garden." The fine trees, the distant prospects, and the principal buildings, still remain; but the garden-scenery has been long since choked by the growth of the forest-trees; and some years ago the fence was removed, and the whole thrown into the park.

South Lodge comes next in order. Soon after the improvements of Hamilton and Lyttelton, "the great Pitt," G. Mason informs us, turned his mind to the embellishment of rural nature, and exercised his talents over Linlithgow Park. The first grounds which he surrounded with "wild and woody, and is diversified with hill and dale." He entertained the idea (and admirably realised it) of making the interior correspondence with the exterior scenery. "This Temple is placed in Observation. But the singular effort of his genius was a successful imitation of the picturesque appearance of a by-lane, on the very principles Price supposes it might be practicable."

The Leasowes were improved about the same time. It was literally a grazing-farm, with a walk, in imitation of a common field, conducted through the several enclosures. Much taste and ingenuity was displayed in dividing it into an extended area, and confining it by distances of the same sort. But root-houses, seats, urns, and inscriptions, were too frequent for the whole to be classed with a common, or even an improved or ornamented English farm. It was, in fact, intended as an emblematical scene to contain moral poetry, and to typify the essence of a sentimental farm. It was just what it ought to have been. We regret to find that Repton should attack the taste of this amiable man, from a misconception, as we presume, of his intentions, by blaming him for not "surrounding his house with such a quantity of ornamental lawn or park only, as might be consistent with his situation, or the nature of his property." We do not see how the poet or the principle of improvement, of mode of improvement, the Leasowes had never been distinguished from places got up by the common routine of professorship. Shenstone broke his heart through the infamous conduct of a Birmingham attorney, in whose hands he had placed the title-deeds of his estate. The farm is now much neglected, though the paths and walks, and the seat, and the root-houses, still remain.

Clarendon and Ether are well known. Both were laid out by Kent and Clarendon, afterwards enlarged, and the house and kitchen-gardens added by Brown. Walpole and Weatley have celebrated both, and also the House by Witte in his poem "The Enchanted Vale of Nature," 1740. Ether no longer exists; but Clarendon is kept up in tolerable style by Prince Leopold.

Persfield was laid out so late as 1750. It is a small park, with an interesting walk, carried along the brow of a romantic rocky river of the river Wye, perhaps as faultless as the nature of the place admits of. "I cannot recollect," says G. Mason, "that any of the scenes on this side of the Wye are the least adulated by the introduction of any puerile appendage whatever."

342. The artists or professors who established the modern style were, Bridgeman, Kent, Wright, Brown, and Eames.

Of Bridgeman we have been able to procure no information. But when he was employed by a mourning-clothe, to a coach-cover in 1719. He soon afterwards came to London, discovered a genius for painting, was sent to Italy, patronised there by Lord Burlington, returned with his lordship, and lived with him in Burlington House till 1748, when he died at the age of 63 years. On his first return, he was chiefly employed to paint historical subjects and ceilings; and the hall at Stowe is from his hand. At least all that was employed as an architect; and, lastly, he was a landscape-gardener. It is not known where he first exercised his genius as a layer out of grounds; probably at Clarendon and Ether, two of his designs. Both minutely described by Weatley, and, judging from the age of the trees, laid out some time between 1722 and 1725. But it was also employed at Boughton, and that was adopted in his improvements of dead trees to heighten the allusion to natural woods. Mason, the poet, mentions Kent's Eslysian scenes in the highest style of panegyric, and observes in a note, that he praised a landscape-sheltered with each other in his more finished pieces, in the manner described in the 14th and 15th books of his "Observations." According to my own observation, not a spot in England not since been done by the most deservedly admired designers, by Southcotche, Hamilton, Lyttelton, Pitt, Shenstone, Morris, for themselves, and by Wright for others, all that has been written on the subject, even the Gardening Didactic Poem and the Didactic Essay on the Picturesque, have proceeded from Kent. Had Kent never exterminated the bounds of regularity, never actually traversed the way to freedom of manner, would any of these celebrated artists have found it of themselves? Theoretical hints from the highest authorities had evidently long existed without sufficient effect. And had not these great masters actually formed many Kent's examples? or inspired them with the design of executing works or the sub- quent writers on gardening have been enabled to collect materials for precepts, or stores for their imaginations?" (Essay, &c. p. 112.),

Wright seems to have been in some repute at the time of Kent's death. "His birth and education," G. Mason informs us, were above pleasing; he understood drawing, and sketched plans of his designs; but never contracted for work, which might occasion his not being applied to by those who consider nothing so much as having trouble taken off their hands." At Becket, the seat of Lord Barrington, he produced an admirable plan, and small proved to be a landscape-gardener, and was appointed to the design and superintendence of that which has by far the greatest part of his popularity. The fashion of employing him continued, says G. Mason, not only to 1768, but to the time of his death, many years afterwards. Repton has given a list of his principal works, among which Cranbrooke and Copped Heath are the two last new places which he formed, including at Great Dunmow, the management and offices, as well as the grounds. The places he altered are beyond all reckoning. Improvement was the passion of the day; and there was scarcely a country-gentleman who did not, on some occasion or other, consult the royal gardener. Mason, the poet, praises this artist, and Lord Walpole apologises for not praising him. Daines Barrington says, "Kent has been succeeded by Brown, who hath undoubtedly great merit in laying out pleasure-gounds; but I conceive both in Brown, who hath in some of the garden-gardener of old Stowe, than of Poussin or Claude Lorrain. I could wish, there-
fore, that Gainsborough gave the design, and that Brown executed." The works and memory of Brown have been very largely attacked by Knight and Price, and strenuously defended by Repton, who styles him "the great self-taught predecessor." "Brown," observes G. Mason, "always appeared to myself in the light of an egregious mannerist; who, from having acquired a facility in shaping surfaces, grew fond of exhibiting that talent, and exerted it in the design of narrow and left mean alleys, and left the execution of them to his great self-taught predecessor. The incongruity of this plan stuck most of the neighbouring gentlemen, but was defended by the artist himself, under shelter of the epithet 'playful,' totally misapplied." (Essay on Design, p. 130, 2d edit. 1795.)

That Brown must have possessed considerable talents, the extent of his reputation abundantly proves; but it has been inferred with much of that taste for picturesque beauty which distinguished the taste of Kent, Hamilton, and Shenstone, we think will hardly be asserted by any one who has observed attentively such places as are known to be his creations. Whatever be the extent or character of the surface, there is always a narrow and left mean alley, a belt, and a rech or two of a tame river on different levels. This description, in short, will apply to almost every place in Britain laid out from the time (about 1740) when the passion commenced for new-modelling country-seats, to about 1765 or 1770, when it in a great measure ceased. The leading outline of this plan of improvement was easily recollected and easily applied; the great demand produced abundance of artists; and the general appearance of the country so rapidly changed under their operations, that in 1774, Sir William Chambers declared, that if the maids were not checked, in a few years longer there would not be found three trees in a line from the Land's-end to the Tweed. Brown, it is said, never went out of England, but he sent pupils and plans to Scotland and Ireland; and Paulowsky, a seat of the late emperor Paul, near Petersburg, is said to be from his design. Brown, as far as we have learned, could not draw, but had assistants, who made out plans of what he intended. He generally contracted for the execution of the work. He amassed a handsome fortune, and his son Launiecot has sat in several parliaments.

The immediate successor of Brown was his nephew, Holland, who was more employed as an architect than as a landscape-gardener, though he generally directed the details of his works. He was succeeded, for a time, by the former capacity. Holland, we believe, retired from business some years ago. Esaces is the next artist that deserves to be mentioned; of him, however, we know little more than that he is mentioned in terms of respect by G. Mason.

343. The authors who established the modern style are, Addison, Pope, Shenstone, G. Mason, Wheatley, and Mason, the poet.

Addison's Spectators have been already referred to. Pope's Epistle to Lord Burlington has also been noticed, as well as Shenstone's Poems and Thoughts; the latter was published in 1718, the latter in 1749.

G. Mason's Essay on Design in Gardening, from which we have so frequently quoted, was first published in 1768, and afterwards greatly enlarged in 1793. It is more a historical and critical work than a didactic performance. Mason was an excellent classical scholar: he lived much alone, and almost always in London, being connected with the Sun Fire Office.

Wheatley's Observations on Modern Gardening, published in 1776, is the grand fundamental and standard work on English gardening. It is entirely analytical; treating, first, of the materials, then of the scenes, and lastly of the whole. The style is admirable, as the elegant style is admired. His general observations are accompanied by descriptions with which his investigations have been largely copied and amply praised by Alison, in his work on taste. The book was soon translated into the continental languages, and is judiciously praised in the Mercure de France, Journal Encyclopédique, and Wieland's Journal. G. Mason alone dissent from the general opinion, enlarging on the very few faults or peculiarities which are to be found in the book. Wheatley, or Whateley, (for so little is known of this eminent man, that we have never been able to ascertain satisfactorily the orthography of his name,) was proprietor of Nonsuch Park, in Surrey, and was secretary to the Earl of Suffolk. He published only this work, soon after which he died. After his death, some remarks on Shakespeare, from his pen, were published in a small 12mo volume.

The English Garden, a poem by W. Mason, was published in four different books, the first of which appeared in 1792. The exception to the general opinion, in which four great artists are agreed. The precepts for planting are particularly instructive. On the whole, the work may be classed with the Observations of Wheatley; and these two books may be said to exhibit a clear view of the modern style, as first introduced and followed by liberal and cultivated minds; whilst the Dissertation on Ornamental Gardening, by Sir William Chambers, holds up to ridicule the absurd limitations of uncultivated amateurs and professors, who have no other qualifications than those acquired in laboring with the spade under some celebrated artist. Mason was a clergyman, resident in Yorkshire, and died in 1797.

344. The partial corruption of the modern style took place as soon as it became fashionable; though it may be true, that "in all liberal arts, the merit of transcendent genius, not the herd of pretenders, characterises an era," yet in an art like that of laying out grounds, whose productions necessarily have such an influence on the general face of a country, it is impossible to judge otherwise of the actual state of the art, than from the effect which is produced. This effect, about forty years ago, when clumps and belts blotted every horizon, could never be mistaken for that intended by such professors as Kent, or such authors as Wheatley and Mason. The truth is, such was the rage for improvement, that the demand for artists of genuine taste exceeded the regular supply; and, as is usual in such cases, a false article was brought to market, and imposed on the public. A liberal was thus for a time reduced to a mechanic art, and a new character given to modern improvements, which, from consisting in a display of ease, elegance, and nature, according to the situation, became a system of set forms, indiscriminately applied in every case. This system was in fact more formal, and less varied, than the ancient style to which it succeeded, because it had fewer parts. An ancient garden had avenues, alleys, streets, pates-d'oeu, pelotons or platons (square clumps), circular masses, rows, double and single, and strips, all from one material, wood; but the modern style, as now degraded, had only three forms, a clump, a belt, and a single tree. Place the belt in the circumference, and distribute the clumps and single trees within, and all that respects wood in one of these places is finished. The professor required no further examination of the ground than what was necessary to take the levels for forming a piece of
water, which water uniformly assumed one shape and character, and differed no more in different situations, than did the belt or the clump. So entirely mechanical had the art become, that any one might have guessed what would be the plan given by the professor before he was called in; and Price actually gives an instance in which this was done. The activity of this false taste was abated in England before our time; but we have seen in Scotland, between the years 1795 and 1805, we believe, above a hundred of such plans, in part formed by local artists, but chiefly by an English professor, who was in the habit of making annual journeys in the north, taking orders for plans, which he got drawn on his return home, not one of which differed from the rest in any thing but magnitude. These plans were, in general, mounted on linen, which he regularly purchased in pieces of some hundreds of yards at a time, from a celebrated bleachfield adjoining Perth.

345. The monotonous productions of this mechanical style soon brought it into disrepute; and proprietors were ridiculed for expending immense sums in destroying old avenues and woods, and planting in their room young clumps, for no other reason than that it was the fashion to do so.

The first symptoms of disapprobation that were ventured to be uttered against the degradation of the new taste, appear to be contained in an epistolary novel, entitled Village Memoirs, published in 1775, in which the professors of gardening are satirised under the name of Layout. A better taste, however, than that of Layout is acknowledged to exist, which the author states, "Shenstone and nature to have brought us acquainted with." Most of the large gardens are said to be laid out by some general undertaker, "who introduces the same objects at the same distances in all." (p. 143.) The translation of Girardin De la Composition des Paysages, ou des Moyens d'embellir la Nature autour des Habitations, in joignant l'agréable à l'utile, &c. accompanying the English, is an excellent historical preface by Daniel Malthus, Eq. in 1763, must have had considerable influence in purifying the taste of its readers. A poem in Dodsley's collection, entitled, Some Thoughts on Building and Planting, addressed to Sir James Lowther, Bart. published in the same year, and in which the poet recommends, that

"Fashion will not the works direct,
But reason be the architect."

must have had some effect. But the Essay on Prints, and the various picturesque tours of Gilpin, published at different intervals from 1788 to 1796, had the principal influence on persons of taste. The beauties of light and shade, outline, grouping, and other ingredients of picturesque beauty, were never before exhibited to the English public in popular writings. These works were eagerly read, and brought about that general study of drawing and sketching landscape among the then rising generation, which has ever since prevailed; and will do more, perhaps, than any other class of studies, towards forming a taste for the harmony and connection of natural scenery, the only secure antidote to the revival of the distinctness and monotonous which characterise that which we have been condemning.

346. The monotonous style has been ably exposed by Price and Knight. The Essays on the Picturesque, of the former, and the poem of the latter, though verging on the opposite extreme of the evil they wished to remove, have greatly improved the taste of proprietors and patrons.

The object of The Landscape, a didactic poem, is to teach the art of creating scenery more congruous and picturesque than what is met with in that " tiresome and monotonous scene called Pleasure-ground." Price's Essays on the Picturesque, and on the use of studying Pictures, with a view to the improvement of real Landscape, are written with the same intention; but, as might be expected from a prose work, enter on the subject much more at length. In order to discover "whether the present system of improving is founded on any just principles of taste," Price begins by enquiring, "whether there is any standard, to which, in point of grouping and of general composition, works of this sort can be referred; any authority higher than that of the persons who have gained the most general and popular reputation by their works, and whose method of conducting them has had the most extensive influence on the general taste." This standard (which, it will be recollected by the candid reader, is desired only for what relates to grouping and composition, not to utility and convenience, as some have unfairly asserted) Price finds in the productions "of those great artists, who have most diligently studied the beauties of nature, both in their grandest and most general effects, and in their minutest detail; who have observed every variety of form and of color; have been able to select and combine; and then, by the magic of their art, to fix upon the canvass all these various beauties." Price recommends the study of the principles of painting, "not to the exclusion of nature, but as an assistant in the study of her works." He points out and illustrates two kinds of beauty in landscape; the one the picturesque, characterised by roughness, abruptness, and sudden variation; the other beauty in the more general acceptance, characterised by smoothness, undulations, intermixed with a certain degree of roughness and variation, producing intricacy and variety. Such beauty was made choice of by Claude in his landscapes, and such, he thinks, particularly adapted to the embellishment of artificial scenery. These principles are applied by Price, in a very masterly manner, to wood, water, and buildings.

347. The reformation in taste contended for by Price and Knight was, like all other proposals for reform, keenly opposed by professors, by a numerous class of mankind who hate innovation, and with whom "whatever is is right," including perhaps some men of taste, who had no feeling for the picturesque, or had mistaken the object of the book. The first answer to Price's work, was a letter by Repton, in which candor obliges us to state,
that the latter has misrepresented his antagonist's meaning, by confounding the study of pictures with that of the study of the principles of painting. Price published an able answer to this production, which, he informs us, was even more read than the original essays. Two anonymous poems of no merit made their appearance, as satires on The Landscape, and indirectly on the Essays on the Picturesque. The Review of the Landscape, and of an Essay on the Picturesque, &c. by Marshall, was published in 1795. There can scarcely be any thing more violent than this publication. The local critics brought forward all sorts of reasons against the use of the study of pictures, and deny (with truth perhaps as to themselves) the distinct character of the picturesque. Mr. Price they treat as "a mere visionary amateur," and Knight as "a Crab-street poet, who has probably no other garden than the pot of mint before his windows."

The opinion of Professor Dugald Stewart, as given incidentally in his Philosophical Disquisitions on the Beautiful, (Essays, p. 283. 1810. 4to. edit.) is of great value. He says, "As to the application of the knowledge thus acquired from the study of paintings, to the improvement of natural landscape, I have no doubt, that to a superior understanding and judgment, those of Price, whose opinions he often suggests, furnish him hints to improve his planning. As the standard to which the ultimate appeal is to be made, it would infallibly cover the face of the country with a new and systematical species of affectation, not less remote than that of Brown from the style of gardening which he wishes to recommend; let painting be allowed its due praise in quickening the attention of visitors of rural scenery to their farther embellishment; and in holding up a standard, from age to age, to correct the caprices of fashionable innovations; but let our taste for these beauties be chiefly formed on the study of nature herself; nor let us ever forget so far what is due to her indisputable and salutary prerogative, as their crest an enmarchement upon it by laws, which derive the whole of their validity from her own sanction." (p. 287.)

348. To draw a fair conclusion from these different opinions, it is necessary to take the whole of them, and the general scope of the authors into view. From the vein of excellent sense which pervades Wyndham's letter, and particularly the latter part of it, which we have extracted entire, it is impossible to avoid suspecting, either that there is a culpable obscurity in the works referred to, or that Wyndham had not sufficiently, if at all, perused them. We are inclined to believe that there is some truth in both suppositions. We have no hesitation, however, both from a mature study of all the writings of these gentlemen, relating to this subject, as well as a careful inspection of their own productions, in saying, that there is not an opinion in the above extract, to which Price and Knight would not at once assent. Knight's directions, in regard to congruity and utility, are as distinct as can well be expected in a poem. Price never entered on the subject of utility. His works say, "Your object is to produce beautiful landscapes; at least this is one great object of your exertions. But you produce very indifferent ones. The beauty of your scenes is not of so high a kind as that of nature. Examine her productions. To aid you in this examination, consult the opinions of those who have gone before you in the same study. Consult the works of painters, and learn the principles which guided them in their combinations of natural and artificial objects. Group your trees on the principles they do. Connect your masses as they do. In short, apply their principles of painting whenever you intend any imitation of nature, for the study of nature and of painting are the same."

Are we to apply them in every case? Are we to neglect regular beauty and utility? Certainly not, that would be inconsistent with common sense.
349. The taste of the present day in landscape-gardening may be considered as comparatively chastened and refined by so much discussion, so many errors and corrections, and a great many fine examples. It is also more liberal than it was half a century ago; admitting the use of the beauties of every style, even the geometric, as occasion requires; in short, considering beauty as always relative to the state of society; and in gardening, even to the state of the surrounding country. The principal artist of the present period, or that which has intervened since the death of Brown and Eames, was the late H. Repton, Esq. This gentleman, from being an amateur, began his career as professor of landscape-gardening about thirty years ago (1788); and till a sort of decline or inactivity of taste took place ten or twelve years since, he was extensively consulted. Though at first an avowed defender and follower of Brown, he has gradually veered round with the change effected in public opinion by the Essays on the Picturesque, so that now, comparing his earlier works of 1795 and 1805, with his Fragments on Landscape Gardening, published in 1817, he appears much more a disciple of Price than a defender of his "great self-taught predecessor." Repton was a beautiful draftsman, and gave, besides plans and views, his written opinion in a regular form, generally combining the whole in a manuscript volume, which he called the red book of the place. He never, we believe, undertook the execution of his plans; nor has, as far as we are aware, been employed out of English, but Valleyfield, in Perthshire, was visited by his two sons, and arranged from their father's designs. The character of this artist's talent seems to be cultivation rather than genius, and he seems more anxious to follow than to lead, and to gratify the preconceived wishes of his employers, and improve on the fashion of the day, than to strike out grand and original beauties. This, indeed, is perhaps the most useful description of talent both for the professor and his employers. Repton's taste in Gothic architecture, and in terraces, and architectural appendages to mansions, is particularly elegant. His published Observations on this subject are valuable, though we think otherwise of his remarks on landscape-gardening, which he look upon as puerile, wanting depth, often at variance with each other, and abounding too much in affectation and arrogance. On the whole, however, we have no hesitation in asserting, that both by his splendid volumes, and extensive practice among the first classes, he has supported the credit of this country for taste in laying out grounds. Repton was born near Felbrig, in Norfolk, and died at Hare-street, in Essex, in 1817.

350. The principal country-seats which display the modern taste of laying out grounds, will be found arranged in the order of the counties in Part IV. of this work, Book I. and Chapter II.

Subsect. 2. Gardening in Scotland, as an Art of Design and Taste.

351. Gardening was introduced into Scotland by the Romans, and revived by the religious establishments of the dark ages.

352. In the sixth century, is supposed to have been formed, the garden of the abbey of Icolmkill, in the Hebrides. It is thus noticed by Dr. Walker (Essays, vol. ii. p. 5.), from its remains as they appeared in the end of the eighteenth century. "On a plain adjoining the gardens of the abbey, and surrounded by small hills, there are vestiges of a large piece of artificial water, which has consisted of several acres, and been contrived both for pleasure and utility. Its banks have been formed by art into walks, and though now a bog, you may perceive the remains of a broad green terrace passing through the middle of it, which has been raised considerably above the water. At the place where it had been dammed up, and where there are the marks of a sluice, the ruins of a mill are still to be seen, which served the inhabitants of the abbey for grinding the corn. Pleasure-gardens of this kind," adds Dr. Walker, "and a method of dressing grain still unpractised in these remote islands, must, no doubt, have been considered in early times, as matters of very high refinement."

353. In the twelfth century, Chalmers informs us (Caledonia Depicta, vol. i. p. 801.), "David I. had a garden at the base of Edinburgh castle. This king," he adds, "had an opportunity of observing the gardens of England under Henry I. when Norman gardening would, no doubt, be prevalent;" and we may reasonably suppose that he was prompted by his genius to profit from the useful, and to adopt the elegant, in that agreeable art.

354. During the greater part of the fourteenth century, Scotland was in a state of intestine war; but in that succeeding, it is generally believed architecture and gardening were encouraged by the Jameses. James I., as we have seen (319.) admired the gardens of Windsor, in 1420, and having been in love there, and married an English woman, would in all probability imitate them. He is described in the Chronicles of Scotland as "an excellent man, and an accomplished scholar. At his leisure hours he not only indulged himself in music, in reading and writing, in drawing and painting; but when the circumstances of time and place, and the taste and manners of those about him made it proper, he would sometimes instruct them in the art of cultivating kitchen and pleasure
gardens, and of planting and engraving different kinds of fruit-trees.” (Scoticron. lib. xvi. cap. 30.)

355. In the middle of the fifteenth century, James III. is described by Pitcscotte, as “delighting more in music and police (probably from the French polir, to remove, level, or improve; or from a corruption of se polir, to improve one’s self,—levelling and smoothing the grounds about a house, being naturally the first step after it is built), and building, than he did in the government of his realm.” The general residence of this monarch was Stirling Castle; and a piece of waste surface in the vale below is said to have been the site of the royal gardens. Enough remains to justify a conjecture, that at this early period they displayed as much skill as those of any other country. We allude to a platform of earth resembling a table, surrounded by turf seats, or steps rising in gradation, the scene, no doubt, of rural festivities.

356. In the middle of the sixteenth century, the Regent Murray had a garden in the neighbourhood of Edinburgh, which still exists. It contains some venerable pear-trees, a magnificent weeping thorn-tree of great age, and the remains of elm-bowers, which have doubtless in their time sheltered the fair queen of Scots, but the interwoven boghts of which now appear in the shape of fantastically bent trunks, thin of spray and leaves. (Hort. Tour, &c. p. 226.)

357. There are various remains of gardens of the fifteenth and sixteenth centuries in Scotland. At the palace of Falkland is a large square enclosure, on a dull flat; in which there exist only a few stunted ash-trees, though the boundary stone wall is still a formidable fence. The gardens of Holyrood House appear to have been exceedingly confined; the boundary wall only remains, and there are some indications of the rows of trees which stood in the park, which seems to have extended to the base of the adjoining hill, Arthur’s Seat. The palace of Scone, we learn from Adanson, a poet of the seventeenth century, was surrounded by “gardens and orchards, flowers and fruits;” and the park, in which are still some ancient trees, “abounded in the hart and fallow deer.” Generally a few old trees in rows adjoin the other royal residences, and oldest baronial castles; but they give no indications of the extent to which art was carried in their disposition.

358. During the seventeenth century, a few gardens must have been formed in Scotland. About the end of this century, the grounds of the Duke of Hamilton were planted, in all probability by a French artist. The design of Chatelherault, an ornamental appendage to the palace of Hamilton, is named after, and formed in imitation of, the residence of that illustrious family in France, laid out by Le Notre.

359. About the beginning of the eighteenth century, the Earl of Lauderdale is said to have sent plans, sections, and sacks of earth from his domain at Hatton, to London and Wise, in London; and these artists, it is added, formed a plan, and sent down a gardener to superintend its execution. Hatton is still a fine old place; but has long changed its possessor.

360. English artists were called into Scotland during this century. Switzer, Laurence, and Langley mention in their works, that they were frequently called into Scotland to give plans of improvement. Some of these gentlemen resided a considerable time in Edinburgh, as he there published, in 1717, a tract on draining, and other useful and agricultural improvements. The Earls of Stair and Haddoing (who wrote on trees), both great planters, about this time, probably consulted them; as would, perhaps, Fletcher of Saltoun, the proprietors of Duncan’s Castle, Barnton, Summerston Hall, Gogar, and particularly Craigie Hall, a residence laid out with much art and taste, and next in rank, in these respects, to Hatton. New Liston, Dalkeith House, Hopeton House, and various other places near Edinburgh, are also in Switzer’s style. New Liston and Hopeton House, planted, we believe, from 1756 to 1760, were probably the last considerable seats laid out in the new style in Scotland.

361. The modern style was first introduced into Scotland by the celebrated Lord Kames, who, some time between 1740 and 1750, displayed it on his own residence at Blair Drummond. An irregular ridge, leading from the house, was laid out in walks, commanding a view, over the shrubs on the declivity, of portions of distant prospect. One part of this scene was composed entirely of evergreens, and formed an agreeable winter-garden. Lord Kames did not entirely reject the ancient style, either at Blair Drummond, or in his Essay on Gardening and Architecture, published in the Elements of Criticism. In that short but comprehensive essay, he shows an acquaintance with the Chinese style, and the practice of Kent; admits both of absolute and relative beauty as the objects of gardening and architecture, and from this complex destination, accounts for that difference and waving of taste in these arts, “greater than in any art that has but a single destination.” (Vol. ii. p. 431. 4th edit. 1769.)

Lord Kames’s example in Scotland may be compared to that of Hamilton or Shenstone in England; it was not generally followed, because it was not generally understood. That the Elements of Criticism, though long since obsolete as such, tended much to purify the taste of the reading class, there can be no doubt. Every person also admired Blair Drummond; but as every country-gentleman could not bestow sufficient time and attention to gardening to be able to lay out his own place, it became necessary to have recourse to artists; and, as it happened, those who were employed had acquired only that habit of mechanical imitation which copies the most obvious forms, without understanding the true merits of the original. In short, they were itinerant pupils of Brown, or profession in his school, who resided in Scotland; and thus it is, that after commencing in the best taste, Scotland continued, till within the last twenty years, to patronise the very worst.

362. The grounds of Duddington House may be referred to as a contrast to the style of
Blair Drummond, and a proof of what we have asserted in regard to the kind of modern landscape-gardening introduced to Scotland. This seat was laid out about the year 1750. The architect of the house was Sir William Chambers; the name of the rural artist, whose original plans we have examined, was Robertson, nephew to the king’s gardener of that name, sent down from London. We know of no example in any country of so perfect a specimen of Brown’s manner, nor of one in which the effect of the whole, and the details of every particular part, are so consistent, and co-operate so well together in producing a sort of tame, spiritless beauty, of which we cannot give a distinct idea. It does not resemble avowed art, nor yet natural scenery; it seems, indeed, as if nature had commenced the work and changed her plan, determining no longer to add to her productions those luxuriant and seemingly superfluous appendages which produce variety and grace. The trees here, all planted at the same time, and of the same age, seem to grow by rule. The clumps remind us of regularly tufted perukes. The waters of the same river neither dare to sink within, nor to overflow its banks; the clumps keep at a respectful distance; and the serpentine turns of the roads and walks, seem to hint that every movement to be made here, must correspond.

The extent of Duddingston, we suppose, may exceed 300 acres. The house is placed on an eminence in the centre, from which the grounds descend on three sides, and on the remaining side continue on a level till they reach the boundary belt. This belt completely encircles the whole; it is from 50 to 200 feet wide, with a turf drive in the middle. One part near the house is richly varied by shrubs and flowers, and kept as garden-scenery; in the rest the turf is mown, but the ground untouched. A string of wavy canals, on disposal of these seats, and from other open glades or vistas left in the inside of the belt. The outer margin of this plantation is every where kept perfectly entire, so that there is not a single view but what is wholly the property of the owner; unless in one instance, where the summit of Arthur’s Seat, an adjoining hill, is caught by the eye from one part of the belt, over the tops of the trees in its opposite periphery. That this place has, or had in 1788, great beauties, we do not deny; but they are beauties of a peculiar kind, not of general nature—not the beauties of Blair Drummond, or such as a liberal and enlightened mind would desire to render general; but in great part such as Sir William Chambers holds up to ridicule in his Dissertation on Oriental Gardening (see his Introduction, p. 6–11); and Price, in his Essay on the Picturesque. Yet Duddingston may be reckoned the model of all future improvements in Scotland, till within the last twenty years. The same artist laid out Livingston, effected some improvements at Hope- ton House, Dalkeith, Dalhouse, Nithdy, the Whim, Moresoun, various other places near Edinburgh, and some in Ayrshire.

363. No artist of note had hitherto arisen in Scotland in this department of gardening, if we except James Ramsay. This person was employed by Robertson, in Ayrshire, as a mason, but soon displayed a taste for disposing of verdant scenery, and afterwards became a landscape-gardener of considerable repute. He gave ground-plans and drawings in perspective, both of the buildings and verdant scenery. Leith Head, a small place near Edinburgh, is entirely his creation. His style was that of Brown, in his waters and new plantations near the house; but he was less attached to the belt, his clumps were not always regular, and he endeavoured to introduce a portion of third distance into all his views. Ramsay died at Edinburgh in 1794, and this record of his taste is due to his memory.

364. English professors of the modern style have occasionally visited Scotland, and some regularly. From nearly the first introduction of the new style to the present time, annual journeys have been made into Scotland from the county of Durham by the late White, and subsequently by his son. White, senior, we believe, was a pupil of Brown, of much information on country-matters, and generally respected in Scotland. Of his professional talents we have said enough, when we have mentioned their source. Airthie, near Stirling, and Bargany, in Ayrshire, are the principal productions of this family. In what respects the talents of White, junior, differ from those of his father, or whether they differ at all, we are not aware; though we think it highly probable they will partake of the general improvement of the age. We have already mentioned that none of the eminent English artists had ever been in Scotland; but that Valleyfield was laid out from Repton’s designs. Nasmyth, an eminent landscape-painter in Edinburgh, and G. Parkyns, author of Monastic Remains, have occasionally given designs for laying out grounds in Scotland, both in excellent taste.

The country-seats of Scotland are elsewhere described. (Part IV. Book I. Chap. III.)

Subject 3. Gardening in Ireland, as an Art of Design and Taste.

365. Of the ancient state of gardening in Ireland very little is known. A short Essay on the Rise and Progress of Gardening in Ireland, by J. C. Walker, is given in the Transactions of the Royal Irish Academy (vol. xiv. part 3.) from which we shall glean what is available for our purpose.

366. In the time of Queen Elizabeth, Fynnes Morrison, "a minute observer," travelled
through that kingdom. He does not once mention a garden as appertaining either to a castle or a monastery; he only observes, "that the best sorts of flowers and fruits are much rarer in Ireland than in England; which, notwithstanding, is more to be attributed to the inhabitants than to the ayre." In an inedit account of a Tour in 1634, also quoted by Walker (Trans. R. I. A.), Bishop Usher’s palace is said to have a "pretty neat garden.

367. Of remains of ancient gardens in Ireland we may quote a few examples. Some of the largest sculptured evergreens are at Bangor, in the county of Down; and at Thomas-town, in the county of Tipperary, are the remains of a hanging garden, formed on the side of a hill, in one corner of which is a verdant amphitheatre, once the scene of occasional dramatic exhibitions. Blessington gardens, if tradition may be relied on, were laid out during the reign of James II. by an English gentleman, who had left his estate at Byfleet in Sussex, to escape the persecution of Cromwell. In King William’s time, knots of flowers, curious edgings of box, topiary works, grassy slopes, and other characteristics of the Dutch style, came into notice. Rowe and Bullein, Englishmen, who had successively nurseries at Dublin, were in these days the principal rural artists of Ireland; though Switzer and Laurence, as well as Batty Langley, occasionally visited that country.

368. The first attempts to introduce the modern style into Ireland are supposed to have been made by Dr. Delany at Delville near Glassnevin, about the year 1720. Swift has left a poetical description of these scenes. Dr. Delany, Walker says, impressed a vast deal of beauty on a very small spot of ground; softened the obdurate straight line of the Dutch into a curve, melted the terrace into a sloping bank, and opened the walk to catch the incal country. Walsh (History of Dublin, 1820) says, these grounds retain all the stiffness of the old garden. As there existed an intimacy between Pope and Delany, it is supposed the former may have assisted his Irish friend. This example appears to have had the same sort of influence in Ireland, that the gardening of Lord Kames had in Scotland. It gave rise to a demand for artists of the new school; and the market was supplied by such as came in the way. Much less, however, was done in that country, partly from the abundance of picturesque scenery in many districts, and partly from other obvious causes. Mount Shannon, near Limerick, the seat of the late Chancellor Clare, is said to have been laid out from his lordship’s designs, and the recent improvements at Charleville forest, where one of the most comfortable and magnificent castles in Ireland has been executed by Johnson of Dublin, were the joint productions of Lord and Lady Charleville. Walker mentions Marino, Castle-town, Carton, Curraghmore, the retreat of St. Woolstans, and Moyra, as exhibiting the finest garden scenery in Ireland. Powerscourt, and Mucross, near the lakes, are reckoned the most romantic residences, and are little indebted to art. St. Valori, Walker’s own seat, is a beautiful little spot near the well-known village of Bray. Miss Plumeetree mentions Blarney Castle (fig. 31.), as one of the most enchanting spots in the world. There have been delightful shrubberies, which might easily be restored. The castle stands on a rock not very high, and below are fine meadows, with an ample stream flowing through them; there is plenty of wood, and a considerable lake at a short distance from the house, which furnishes excellent trout: in short, nature has left little for art to supply; and yet this charming spot is deserted, abandoned, looking wholly neglected and forlorn. (Residence in Ireland, 1817, 240.)

369. English artists professing the modern style have been but little employed in Ireland, the common practice being to engage a good kitchen-gardener from England, and leave every thing to him. Sutherland was, in 1810, the local artist of greatest repute. A. McLear has since settled in this country, and, from what we know of this artist, we have little doubt he will contribute, in an eminent degree, to establish and extend a better taste than has yet appeared there. W. T. Mackay, curator of the Trinity-college garden, is said to excel in laying out grounds. Though landscape-gardeners from the metropolis have not been called to Ireland, yet it has happily become not an unfrequent practice to employ eminent English architects,—a practice, as far as taste is concerned, certain of being attended with the most salutary effects.

Sect. II. British Gardening, in respect to the Culture of Flowers and Plants of Ornament.

370. Flowers are more or less cultivated wherever gardening is practised; but a particular attention to this department of the art can only take place under circumstances of
ease, and a certain degree of refinement. A taste for fine flowers has existed in Holland and the Netherlands from a very remote period, and was early introduced into England; but when that taste found its way to Scotland and Ireland, is much less certain.

**SUBSEC. 1. Gardening in England, in respect to the Culture of Flowers and the Establishment of Botanic Gardens.**

371. The taste for florists' flowers, in England, is generally supposed to have been brought over from Flanders with our worsted manufactures, during the persecutions of Philip II.; and the cruelties of the Duke of Alva, in 1567, was the occasion of our receiving, through the Flemish weavers, gillyflowers, carnations, and provins roses. But flowers and flowering shrubs were known and prized even in Chaucer's time, as appears from a well-known passage of that poet. An Italian poet published, in 1586, a volume of poems, one of which is *On the Royal Garden*; from this poem it would appear that Queen Elizabeth was attached to the culture of flowers, but few are named either in these poems, or in the description of Theobald's. Parterres seem to have been introduced in the beginning of Queen Elizabeth's reign, and also the tulip, and damask and musk roses. Gerrard, who published his herbal three years before, mentions James Garnet, "a London apothecary, a principal collector and propagator of tulips, for twenty years bringing forth every season new plants of sundry colors not before seen, all which to describe particularly were to roll Sisyphus's stone, or number the sands."

372. One of the earliest notices which we have of a botanic garden in England is that of the Duke of Somerset, at Sion House, in the beginning of this century. It was placed under the superintendence of Dr. Turner, whom Dr. Pulteney considers as the father of English botany. Turner had studied at Bologna and at Pisa, where, as we have already seen (91.), botanic gardens were first formed. After being some years with the Duke of Somerset, he retired from Sion House to Wells, where he had a rich garden, and died there in 1560. About this time existed the botanic gardens of Edward Saintlono, in Somersetshire, James Coel, at Highgate, J. Nasmyth, surgeon to James I., and John de Franqueville, merchant in London. From the care of the latter, Parkinson observes, "is sprung the greatest store that is now flourishing in this kingdom." Gerrard had a fine garden in Holborn, in the middle of the sixteenth century, of which there is a catalogue in the British Museum, dated 1590. This garden was eulogised by Dr. Boyleyn and others his contemporaries. Gerrard mentions Nicholas Lete, a merchant in London, "greatly in love with rare and fair flowers, for which he doth carefully send into Syria, having a servant there, at Aleppo, and in many other countries; for which myself, and the whole land are much bound unto him." The same author also gives due honor to Sir Walter Raleigh, Lord Edward Zouch, the patron of Lobel, who brought plants and seeds from Constantinople, and to Lord Hudson, Lord High Chamberlain of England, who, he says, "is worthy of triple honor for his care in getting, as also for his keeping such rare and curious things from the farthest parts of the world." (*Pulteney's Sketches*, 125.)

373. In the beginning of the seventeenth century, flowers and curious plants appear to have been very generally cultivated. Platt's *Paradise of Flora*, which is the first book that treats expressly on flowers, appeared in 1600. Parkinson published his *Paradisus* in 1629. "A modern florist," observes Dr. Pulteney, "wholly unacquainted with the state of the art at the time Parkinson wrote, would perhaps be surprised to find that his predecessors could enumerate, besides 16 described as distinct species, 120 varieties of the tulip, 60 anemonies, more than 90 of the narcissus tribe, 50 hyacinths, 50 carnations, 20 pink, 30 crocuses, and above 40 of the Iris genus." (*Sketches*, &c. vol. ii. 123.) The laurel, or bay-cherry, was then very rare, and considered as a tender plant, being defended "from the bitterness of the winter by casting a blanket over the top thereof," and the larch-tree was only reared up as a curiosity. Greenhouse-plants were placed in cellars, where they lost their leaves, but those of such as survived shot out again in spring when removed to the open air.

*Flowers were much cultivated in Norwich, from the time of the Flemish weavers settling there. Sir J. E. Smith (Linn. Trans. vol. ii. p. 296) mentions a play called Rhodon and Iris, which was acted at the florists' feast at Norwich, in 1571; a proof that the culture of flowers was in great estimation there at that time; and in 1671 Evelyn mentions Sir Thomas Brown's garden there, as containing a paradise of rarities, and the gardens of all the inhabitants as full of excellent flowers. From Norwich the love of flowers seems to have spread to other manufacturing establishments; and the taste still continues popular, not only there, but among the weavers in Spitalfields, Manchester, Bolton, and most of the commercial towns in Lancashire, and many in Cheshire, Derbyshire, and other adjoining counties. A florists' society is established in almost every town and village in the northern district. These societies have annual shows, as in London and Norwich; and a book, called *The Flower Book*, is published annually in Manchester, containing an account of their transactions, the prizes which have been given, and the new flowers which have been originated.*

*Ham House, the Duke of Lauderdale's, had famous parterres and orangeries at this time. Sir Henry Cole, the well-looked and ornate garden at Kew; and Lady Clarendon, at Swallowfield, who, Evelyn informs us, was well skilled in flowers, had an ample collection at Swallowfield in Berkshire.*

*In the garden of William Coyte, of stubbors, in Essex, the yucca blossomed in 1604, for the first time in England. (Lobel, Hist. Plant.) The place of Royal Herbolist was created by Charles I.; and Parkinson was appointed to fill it.*

Queen
Mary appointed Plunket to be his successor, "a man distinguished for botanical knowledge." Under this botanist's directions, collectors were despatched to the Indies in search of plants.

Tradescant's botanic garden at Lambeth was established previously to 1629. Tradescant was a Dutchman, and gardener to Charles I. In 1656, his son published a catalogue of this garden, and of the museum, which both of them had collected. Weston observes (Catalogue of Authors on Gardening, 30) that the garden having for some years lain waste, on the 1st of May, 1745, William Watson, F. R. S., having visited its site, found many of the exotics remaining, having endured two great frosts in 1729 and 1740. A curious account of the garden is given by Sir W. Watson, in the Philosophical Transactions. (vol. xl.) Tradescant left his museum to E. Ashburnham, who lodged in his house. Mrs. Tradescant contested the will, and on losing the cause drowned herself.

The Chelsea botanic garden seems to have existed about the middle of this century. In 1635, Evelyn visited Watts, their head gardener. "What was very ingenious, was the subterranean heat conveyed by means of a stove under two conservatories, all vaulted with brick, so that he has the door and windows open in the hardest frosts, excluding only the snow." (Memoirs, &c. vol. i. 506.) In Watts's garden was a tulip-tree, and in the hot-house a tea-shrub. (Ray.) The ground occupied by this garden was rented from Sir Hans Sloane, for 5l. a year, and fifty new plants to be presented annually to the Royal Society, till their number amounted to two thousand.

Various private botanic gardens existed at the end of this century. That of the celebrated naturalist Ray, in Essex, Dr. Uvedale's, at Enfield, and especially that of the Duchess of Beaufort, at Badmington, were rich in plants; but that of Sir Hans Sloane, at Chelsea, surpassed them all.

374. A public botanic garden in England was first founded at Oxford, in 1632, nearly a century after that at Padua. This honor was reserved for Henry, Earl of Danby, who gave for this purpose five acres of ground, built green-houses and stoves, and a house for the accommodation of the gardener, endowed the establishment, and placed in it, as a supervisor, Jacob Bobart, a German, from Brunswick, who lived, as Wood tells us, in the garden-house, and died there in 1697. The garden contained at his death above 1600 species. Bobart's descendants are still in Oxford, and known as coach-proprietors.

375. Green-houses and plant-stoves seem to have been introduced or invented about the middle of the seventeenth century. They were formed in the Altorf garden in 1645. Evelyn mentions Loader's orangery in 1662, and the green-house and hot-house at Chelsea are mentioned both by that author and Ray in 1685.

376. During the whole of the eighteenth century, botany was in a flourishing state in England. Previously to this period the number of exotics in the country probably did not exceed 1000 species: during this century above 5000 new species were introduced from foreign countries, besides the discovery of a number of new native plants. Some idea may be formed of the progress of gardening, in respect to ornamental trees and shrubs, from the different editions of Miller's dictionary. In the first edition in 1724, the catalogue of evergreens amounts only to twelve. The Christmas-flower and aconite were then rare, and only to be obtained at Fairchild's at Hoxton: only seven species of geraniums were then known. Every edition of this work contained fresh additions to the botany of the country. In the preface to the eighth and last edition, published in 1768, the number of plants cultivated in England is stated to be more than double those which were known in 1731. Miller was born in 1691; his father was gardener to the Company of Apothecaries, and he succeeded his father in that office in 1729, upon Sir Hans Sloane's liberal donation of near four acres to the Company. He resigned his office a short time before his decease, which took place in 1771, and was succeeded by Forsyth, who was succeeded by Fairbairn, and the last by Anderson the present curator.

377. As great encouragers of botany during this century, Miller mentions in 1724, the Duke of Chandos, Compton Speaker of the House of Commons, Dubois of Mitcham, Compton Bishop of London, Dr. Uvedale of Enfield, Dr. Lloyd of Sheen. Dr. James Sherrard, apothecary, had one of the richest gardens England ever possessed at Eltham. His gardener, Knolton, was a zealous botanist, and afterwards, when in the service of the Earl of Burlington, at Londoensborough, discovered the globe conferta. Dr. Sherrard's brother was consul at Smyrna, and had a fine garden at Sedoikio, near that town, where he collected the plants of Greece and many others. The consul died in 1728, and the apothecary in 1737. Fairchild, Gordon, Lee, and Gray of Fulham, eminent nurserymen, introduced many plants during the first half of the century. The first three corresponded with Linnaeus. Collinson, a great promoter of gardening and botany, had a fine garden at Mill-hill. Richard Warner had a good botanic garden at Warnford Green. The Duke of Argyle, styled a tree-monger by Lord Walpole, had early in this century a garden at Hounslo, richly stocked with exotic trees. A number of other names of patrons, gardeners, and authors, equally deserving mention, are necessarily omitted. Dr., afterwards Sir John Hill, had a botanic garden at Bayswater; he began to publish in 1751, and produced numerous works on plants and flowers, which had considerable influence in rendering popular the system of Linnaeus, and spreading the science of horticulture, and a taste for ornamental plants. In 1775 Drs. Fothergill and Pitcairn sent out Thomas Blaikie (170.) to collect plants in Switzerland, and this indefatigable botanist sent home all those plants mentioned in the Hortus Kewensis, as introduced by the two Doctors.

378. During the latter part of the eighteenth century, Hibbert, of Chalfont, and
Thornton, of Clapham, opulent commercial men, may be mentioned as great encouragers of exotic botany. The collection of Heaths, Banksias, and other Cape and Botany Bay plants, in the Clapham garden, was most extensive; and the flower-garden, one of the best round the metropolis. The Duke of Marlborough, while Marquis of Blandford, formed a collection of exotics at White Knights, surpassed by none in the kingdom. (Historical Account of White Knights, &c. 1820, quarto.) R. A. Salisbury, one of our first botanists, and a real lover of gardening, had a fine garden and rich collection at Chapel Allerton, in Yorkshire. Subsequently, he possessed the garden formed by Collinson at Mill Hill. Choice collections of plants were formed at the Earl of Tankerville's at Walton, the Duke of Northumberland's at Sion House, at the Comte de Vandes' at Bayswater, Vere's at Knightsbridge, and many other places. Lee, Lodgige, Knight, Colville, and several other nurserymen, might be named as greatly promoting a taste for plants and flowers by their well-stocked nurseries and publications. Of these the Heathery, the Botanical Cabinet, and the Genus Protea, are well known and esteemed works. A grand stimulus to the culture of ornamental plants, was given by the publication of Curtis's Botanical Magazine, begun in 1787, and still continued in monthly numbers. Here the most beautiful hardy and tender plants were figured and described, and useful hints as to their culture added. Other works by Sowerby, Edwards, Andrews, &c. of a similar nature, contributed to render very general a knowledge of, and taste for plants, and a desire of gardens and green-houses, to possess these plants in a living state. Maddock's Florists' Directory, which appeared in 1792, revived a taste for florists' flowers, which has since been on the increase.

379. The royal gardens at Kew were begun about the middle of this century, under the auspices of Frederick, Prince of Wales, the father of George III. The exotic department of that garden was established chiefly through the influence of the Marquis of Bute, a great encourager of botany and gardening, who placed it under the care of W. Aiton, who had long been assistant to Miller, of the Chelsea garden. Sir John Hill published the first Hortus Kewensis in 1768, but subsequent editions have been published under the direction of Aiton, the father and son; the last, in five volumes, the joint production of Dr. Dryander and R. Brown, is reckoned a standard work. A compendium in a pocket-volume has been published, which enumerates about 10,000 species. Sir Joseph Banks gave the immense collections of plants and seeds obtained in his voyages to this garden, and this example has been followed by most travellers, so that it is now the richest in England, as far as respects its catalogue, though it is generally believed a greater, or at least, an equal number of species are actually cultivated in the botanical garden of Liverpool.

380. The Cambridge botanic garden was founded about the middle of the eighteenth century by Dr. Walker. It has chiefly become celebrated for the useful catalogue of plants (Hortus Cantabrigiensis) published by Donn, its late curator. The garden is small, and never at any one time could contain all the plants, to the number of 9000, enumerated in that work. But if ever introduced there, that circumstance is supposed to justify their insertion in the catalogue.

381. The nineteenth century has commenced with the most promising appearances as to floriculture and botany. The Linnean and Horticultural Societies of London have been established; and florists' societies are increasing; and some other gardening and botanical associations forming in the counties. The number of plant-collectors sent out is greatly increased; and not only do societies and public bodies go to this expense, but even private persons and nursery-men. The botanical gardens of Liverpool and Hull have been established, and others are in contemplation.

382. The Liverpool garden owes its origin to the celebrated W. Roscoe. It was begun in 1803, and a catalogue published in 1808 by Shepherd, the curator, containing above 6000 species.

SUBSECTION 2. Gardening in Scotland, in respect to the Culture of Flowers and the Establishment of Botanic Gardens.

383. A taste for florists' flowers, it is conjectured, was first introduced into Scotland by the French weavers, who took refuge in that country in the seventeenth century, and were established in a row of houses, called Picardy-row, in the suburbs of Edinburgh. It seems to have spread with the apprentices of these men to Dunfermline, Glasgow, Paisley, and other places; for in Scotland, as in England, it may be remarked, that wherever the silk, linen, or cotton manufactures, are carried on by manual labor, the operators are found to possess a taste for, and to occupy part of their leisure time in the culture of flowers.

384. The original botanic garden of Edinburgh took its rise about the year 1680, from the following circumstances: "Patrick Murray, Baron of Livingston, a pupil of Dr., afterwards Sir Andrew Balfour, in natural history, formed a collection of 1000 plants at Livingston; but soon afterwards dying abroad, Dr. Balfour had his collection trans-
ferred to Edinburgh, and there uniting it with his own, founded the botanic garden. It had no fixed support for some time; but at length the city of Edinburgh allotted a piece of ground near the College-church, for a public garden, and appointed a salary for its support out of the revenues of the University." (Walker's Essays, 358.) In 1767, the garden was removed to a more eligible situation, considerably enlarged, and a very magnificent range of hot-houses erected under the direction of Dr. John Hope, who first taught the Linnean system in Scotland. This garden, in general arrangement, and in the order in which it is kept, is inferior to none in the kingdom, though at Kew and Liverpool, the collection of plants is necessarily much greater. The collection in 1812, amounted to upwards of 4000 species, among which are some rare acclimated exotic trees, which have attained a great size. This garden was again removed, in 1822, to a situation including sixteen acres, where it is established with extensive hot-houses, and other desiderata, in a very superior style.

385. In the early part of the eighteenth century, this taste was introduced to the higher classes by James Justice, F. R. S., who had travelled on the continent, and spared no expense in procuring all the best sorts of florists' flowers from Holland, and many curious plants from London. Such was his passion for gardening, that he spent the greater part of his fortune at Crichton, near Edinburgh, where he had the finest garden, and the only pine-stove in Scotland, and the largest collection of auriculae, as he informs us, in Europe. In 1755, he published The Scots Gardener's Director, esteemed an original work, and containing full directions, from his own experience, for the culture of choice flowers. About the end of this century, florists' societies which had existed before, but declined with the decline of gardeners' lodges, were revived in Edinburgh; and there are now several in Glasgow, Paisley, and other parts of the country. Those at Paisley are considered remarkable for the skill and intelligence of their members, and the fine pinks and other flowers produced at their shows. (Gen. Rep. of Scot. App. to chap. 2.) The Edinburgh Florists' Society gave rise to the Caledonian Horticultural Society, which was established in 1809, and has greatly promoted this and other branches of gardening in Scotland.

386. In the middle of the eighteenth century, the Marquis of Bute had a rich botanic garden in the island from which he takes his title. Towards the end, a sale botanic garden was formed at Forfar, by Mr. George Donn, a well-known botanist; and another at Monkwood, in Ayrshire, by Mr. James Smith, which contains about 3500 species, chiefly indigenous. At Dalbeth, near Glasgow, T. Hopkirk, a wealthy commercialist, also maintained a respectable assemblage of natives.

387. The nineteenth century will probably witness a great degree of progress in botany and floriculture in Scotland. Notwithstanding the example of Justice in 1750, and the opening of the new botanic garden, with a tolerable collection in 1782, a taste for collections of plants can hardly be said to have existed among the higher classes in Scotland, previously to the present century. Flowers, either gathered, or in pots, were rarely purchased by the inhabitants of the capital, and not at all by those of any of the provincial towns. One, or at most, two green-houses might be said to have supplied all the wants of Edinburgh, till within the last twenty years, and the demand, though increased, is still of a very limited description among the middling classes. A very complete botanic garden has been lately formed at Glasgow, and W. J. Hooker, F. R. S., a distinguished botanist, appointed professor. A new stimulus to the introduction and culture of rare plants will be given by a periodical work, commenced by Dr. Hooker, and devoted to the description of such new plants as flower in Scotland; for variety is useful in many things. Such flowers and exotics as were cultivated in the gardens of country-gentlemen were, till within the last thirty years, grown in the borders of the kitchen-garden, or in the forcing-houses; but it has now become customary to have flower-gardens and hot-houses expressly for plants, as in England. (See Part IV. Book I. Chap. III.)

Subsect. 3. Gardening in Ireland, in respect to Floriculture and Botany.

388. Botany and flower-gardening have been much neglected in Ireland. Parterres, it would appear, (J. C. Walker's Hist.) came into notice during the reign of King William. Dr. Caleb Thirlkeld was among the first of the few who formed private botanic gardens for their own use, and Sir Arthur Rawdon almost the only individual who displayed wealth and taste in collecting exotics. Upon visiting the splendid collection of Sir Hans Sloane, at Chelsea, Sir Arthur, delighted with the exotics there, sent James Harlow, a skillful gardener, to Jamaica, who returned with a ship almost laden with plants, in a vegetating state. For these a hot-house was built at Moyra, in the beginning of Charles the Second's reign, supposed to be the first erection of that kind in Ireland.

389. In 1712, a small collection of plants was cultivated in the garden of the Dublin Medical College.

390. The botanic garden of Trinity College was established in 1786, and though small, yet, as Neill observes, contains a richer and more varied collection than perhaps is to be found anywhere else within the same compass. There is also a botanic garden at Cork.
391. *The botanical garden of the Dublin Society* was established in 1790, chiefly through the exertions of Dr. Walker Wade. It contains upwards of thirty acres, delightfully situated, and very ingeniously arranged.

392. There are a few private collections in Ireland; and one of the best flower-gardens is that of Lord Downes, at Merville, near Dublin; but, in general, it may be stated, that ornamental culture of every kind is in its infancy in that country. Something will probably be effected by the Dublin Horticultural Society, established in 1816.

Sect. III. British Gardening, in respect to its horticultural Productions

393. The knowledge of culinary vegetables and cultivated fruits was first introduced to this country by the Romans; and it is highly probable that the more useful sorts of the former, as the brassica, and onion tribe, always remained in use among the civilised parts of the inhabitants, since *kale and leeks* are mentioned in some of the oldest records, and the Saxon month April was called *Sprout Kale*.

394. The native fruits of the British isles, and which, till the 13th or 14th century, must have been the only sorts known to the common people, are the following: small purple plums, sloes, wild currants, brambles and raspberries, wood strawberies, cranberries, black-berries, red-berries, heather-berries, elder-berries, roan-berries, haws, holly-berries, hips, hazel-nuts, acorns, and beech-mast. The wild apple or crab, and wild cherry, though now naturalised, would probably not be found wild, or be very rare in the early times of which we now speak. The native roots and leaves would be earth-nut, and any other roots not remarkably acid and bitter; and chenopodium, sorrel, dock, and such leaves as are naturally rather succulent and mild in flavor.

395. The more delicate fruits and legumes, introduced by the Romans, would, in all probability, be lost after their retirement from the island, and we may trace with more certainty the origin of what we now possess to the ecclesiastical establishments of the dark ages, and during the reign in England of the Norman line, and the Plantagenets. It may in general be asserted, that most of our best fruits, particularly apples and pears, were brought into the island by ecclesiastics in the days of monastic splendor and luxury, during the 12th, 19th, 14th, and 15th centuries. Gardens and orchards (*horti et ponaria*) are frequently mentioned in the earliest chartularies extant; and of the orchards many traces still remain in different parts of the country, in the form, not only of enclosure-walls and prepared fruit-tree borders, but of venerable pear-trees, some of them still abundantly fruitful, and others in the last stage of decay. Of the state of horticulture previous to the beginning of the 16th century, however, no distinct record exists. About that time it began to be cultivated in England, and at more recent periods in Scotland and Ireland.

396. The earliest notice of English horticulture which we have met with, is in Gale's *History of Ely, and William of Malmsbury*, and belongs to the twelfth century. Brithnod, the first abbot of Ely, in 1107, is celebrated for his skill in gardening, and for the excellent gardens and orchards which he made near that monastery. "He laid out very extensive gardens and orchards, which he filled with a great variety of herbs, shrubs, and fruit-trees. In a few years the trees which he planted and ingrafted, appeared at a distance like a wood, loaded with the most excellent fruits in great abundance, and added much to the commodiousness and beauty of the place." (Gale's *Hist. of Ely*, 2. c. ii.) William of Malmsbury speaks of the abundance of vineyards and orchards in the vale of Gloucester. At Edmondsbury, a vineyard was planted for the use of the monks of that place, in 1140.

397. In the thirteenth century (A. D. 1294), the monks of Dunstable were at much expense in repairing the walls about the garden and herbyary of their priory; and the herbyary mentioned in Chaucer's *Nonne's Priest's Tale*, appears to have been well stored with medical herbs, shrubs, &c. Paris, in describing the backwardness of the seasons in 1297, says, that "apples were scarce, pears still scarcer; but that cherries, plums, figs, and all kinds of fruits included in shells, were almost quite destroyed." (Henry's *Hist.* b. iv. chap. 5. sect. 1.)

398. Previously to the sixteenth century, it is generally said, that some of our most common pot-herbs, such as cabbages, were chiefly imported from the Netherlands, their culture not being properly understood in this country. "It was not," says Hume, "till the end of the reign of Henry VIII. that any salads, carrots, turnips, or other edible roots, were produced in England. The little of these vegetables that was used, was formerly imported from Holland and Flanders. Queen Catherine, when she wanted a salad, was obliged to despatch a messenger thither on purpose." (Hist. of Eng. anno 1547.) Fuller, in 1660, speaking of the gardens of Surrey, says, "Gardening was first brought into England for profit about seventy years ago; before which we fetched most of our cherries from Holland, apples from France, and hardly had a mess of ræth-ripe peas, but from Holland, which were dainties for ladies; they came so far and cost so dear. Since gar-
GARDENING or, and he strawberries but peres wallnuts, grene progress. day. melons &c. says (Itinerary, &c.), that at Morle in Derbyshire, there is as much pleasure of orchards of great variety of fruit, as in any place of Lancashire. The castle of Thornbury, in Gloucestershire, had an orchard of four acres, and there were others at Wreschill on the Ouse.

400. Books on horticulture appeared towards the middle of the sixteenth century. The first treatise of husbandry was a translation from the French, by Bishop Grosshead, in 1500. In 1521, appeared Arnold's Chronicles, in which is a chapter on "The craft of graftying, and plantyinge, and alteringye of fruits, as well in colours as in taste." The first author who treats expressely on gardening is Tusser, whose Five Hundred Points of good Husbandrie, &c. with divers approved Lessons on Hopps and Gardening, &c. was first published in 1517.

Thomas Tusser, (Sir J. Banks in Hort. Trans. i. 150.) who had received a liberal education at Eton school, and at Trinity-Hall, Cambridge, lived many years as a farmer in Suffolk and Norfolk; he afterwards removed to London, where he published the first edition of his work, and died in 1550. In his fourth edition, in 1578, he first introduced the subject of gardening, and has given us not only a list of the fruits, but also of all the plants then cultivated in our gardens, either for pleasure or profit, under the following heads:—

Scots and herbes for the kychen, herbes and rootes for sallets and sawce, herbes and roots to boyle or to butter, strewing herbs of all sorts, herbs, branches, and flowers for windowes and pots, herbs to still in summer, necessarie herbs to grow in the gardens for physick, not reherst before.—This list consists of more than 150 species.

Of fruites he enumerates, apple-trees of all sorts, apricoches, bar-berilles, bolesse black and white, cherries red and black, chestnuts, cornet plums (probably the Common cherry); damisens white and black, fillert red and white, gooseberries, grapes white and red; grene or grass-plums, herttil berries (maccoluma vestibulare), medlars or merles, mulberry, peaches, peaches white, red, and yellow fleshed (called also the orange-peach); pears of all sorts, pear plums, black and yellow, quince trees; raspes, raisons (probably currants), small nuts; strawberries red and white; service trees, wardeens white and red; wallnuts, wheat plums. Other fruits perhaps might have been added, as the aj; that fruit having been introduced previous to 1534, by Cardinal Pole. The orange and pomegranate, which Evelyn, in 1700, says, had stood at Beddington 120 years; and the melon, which, according to Lobel, was introduced before 1570, so that on the whole, we had all the fundamental varieties of our present fruits in the middle of the sixteenth century. The pineapple is the only exception, which was not introduced till 1600.

401. The fertility of the soil of England was depreciated by some in Tusser's time, probably from seeing the superior productions brought from Holland and France. Dr. Boleyn, a contemporary, defends it, saying, "we had apples, pears, plums, cherries, and hops of our own growth, before the importation of these articles into England by the London and Kentish gardeners, but that the cultivation of them had been greatly neglected. He refers as a proof of the natural fertility of the land to the great crop of sea-pease (Pisum maritimum), which grew on the beach between Orford and Aldborough, and which saved the poor in the dearth of 1555. Oldys soon afterwards, speaking of Gerard's fine garden and alluding to the alleged depreciation of our soil and climate, says "from whence it would appear, that our ground could produce other fruits besides hips and haws, acorns and pig-nuts." At this time, observes Dr. Pulteney (Sketches, &c. 118.), "kitchen garden wares were imported from Holland, and fruits from France."

402. During the reign of Elizabeth, horticulture appears to have been in a state of progress. Various works on this branch then appeared, by Didymus Mountain, Hyll, Mascal, Scott, Googe, &c.; these, for the most part, are translations from the Roman and modern continental authors. Mascal is said to have introduced some good varieties of the apple.

403. Charles I. seems to have patronised gardening. His kitchen-gardener was Tradescant, a Dutchman, and he appointed the celebrated Parkinson his herbalist. In 1629, appeared the first edition of this man's great work, in folio, entitled, "Paradisi in sole Paradisus terrestris; or, a Garden of all sorts of pleasant Flowers, with a Kitchen Garden of all manner of Herbs and Roots, and an Orchard of all sort of Fruit-bearing Trees, &c." This, as Neill observes (Ed. Euege. art. Hort.), may be considered as the first general book of English gardening possessing the character of originality. For the culture of melons, he recommends an open hot-bed on a sloping bank, covering the melons occasionally with straw,—the method practised in the north of France at this day. Cauliflowers, celery, and finochio, were then great rarities. Virginia potatoes (our common sort) were then rare; but Canada potatoes (our Jerusalem artichoke) were
in common use. The variety of fruits described, or at least mentioned, appears very great. Of apples there are 58 sorts; of pears, 64; plums, 61; peaches, 21; nectarines, 5; apricots, 6; cherries, no fewer than 36; grape-vines, 23; figs, 3; with quinces, medlars, almonds, walnuts, filberts, and the common small fruits.

404. *Cromwell* was a great promoter of agriculture and the useful branches of gardening, and his soldiers introduced all the best improvements wherever they went. He gave a pension of 100l. a-year to Hartlib, a Lithuanian, who had studied husbandry in Flanders, and published *A Letter to Dr. Beati, concerning the Defects and Remedies of English Husbandry*, and the *Legacy*, both useful works. He was an author, says Harte, who preferred the faulty sublime, to the faulty mediocrity. He recommended the adoption in England of the two secrets of Flemish husbandry, that of letting farms on improving leases, and cultivating green crops.

405. *Charles II.* being restored to the throne, introduced French gardening, and his gardener, Rose, Daines Barrington informs us, "planted such famous dwarfs at Hampton Court, Carlton, and Marlborough gardens, that London, who was Rose's apprentice, in his *Retired Gardener*, published 1667, challenges all Europe to produce the like." Waller, the poet, in allusion to the two last gardens, describes the mall of St. James's park, as:

"All with a border of rich fruit-trees crown'd."

When Quintinye came to England to visit Evelyn, Charles II. offered him a pension to stay and superintend the royal gardens here; but this, says Switzer (*Pref. to Iconographia rustica*), he declined, and returned to serve his own master. Daines Barrington conjectures that Charles II. had the first hot and ice houses ever built in this country, as at the installation dinner given at Windsor, on the 23d of April, 1667, there were cherries, strawberries, and ice-creams. These fruits, however, had been long, as Switzer states, raised by dung-heat by the London gardeners, and the use of ices must have long before been introduced from the continent.

406. *Evelyn* was a distinguished patron of horticulture. On returning from his travels, in 1658 he published his *French Gardener*, and from that time to his death in 1706 continued one of the greatest promoters of our art. In 1664, he published his *Pomona*, and *Calendarium Hortense*; the latter, the first work of the kind which had appeared in this country. In 1658, his translation of Quintinye's work on orange-trees, and his *Complete Gardener* appeared; and his *Acetaria*, in 1669, was his last work on this branch of gardening. Evelyn is universally allowed to have been one of the warmest friends to improvements in gardening and planting that has ever appeared. He is eulogised by Wotton, in his *Reflections on Ancient and Modern Learning*, as having done more than all former ages, and by Switzer, in his historical preface to *Iconographia rustica*, as being the first that taught gardening to speak proper English. In his *Memoirs* by Bray, are the following horticultural notices.

1661. *Lady Brook's at Hackney*: "vines planted in strawberry borders, staked at ten feet distance. I saw the famous queen-pine brought from Barbadoes, and presented to his majesty." Evelyn had seen one four years before, and he afterwards saw the first king-pine presented at the Banqueting-house, and tasted of it. At Kensington Palace is a picture, in which Charles II. is receiving a pine-apple from his gardener, Rose, who is presenting it on his knees.

1665. *At Sir William Temple's at East Sheen*, the most remarkable things "are his orangeries and gardens, where the wall fruit-trees are most exquisitely nailed and trained, far better than I have noted any where else." Sir William has some judicious remarks on the soils and situations of gardens, in his *Essay* written in 1668. He was long ambassador at the Hague, and had the honor, as he informs us, and as Switzer confirms, of introducing some of our best peaches, apricots, cherries, and grapes.

1678. *At Ken Garden* (*Memoirs*, vol. ii. p. 17). "Sir Henry Capel has the choicest plantation of fruit in England, as he is the most industrious and most understanding in it." Daines Barrington (*Archeologia*, viii. 122.) considers Lord Capel to have been the first person of consequence in England, who was at much expense in his gardens, having brought over with him many new fruits from France.

407. *During the eighteenth century*, the progress of horticulture, as of every other department of gardening was rapid. This will appear from the great number of excellent authors who appeared during this period, as Millar, Lawrence, Bradley, Switzer, in the first half; and Hitt, Abercrombie, Marshal, M'Phail, and others in the latter part of the period. Switzer was an artist-gardener and a seedsman, and laid out many excellent kitchen and fruit gardens, and built some hot-walls and forcing-houses.

408. *Forcing-houses and pine-stoves* appear to have been introduced in the early part of the eighteenth century; but forcing by hot beds and dung placed behind walls of boards were, according to Switzer (*Fruit Gardener*) and Lord Bacon, in use for an unknown length of time.

409. *The pine-apple* was first successfully cultivated by Sir Matthew Decker, at Richmond, in 1719. Warner, of Rotherhithe, excelled in the culture of the vine, and raised from seed the red, or Warner's Hambrough, a variety which still continues to be much esteemed.

410. *In the last year of the seventeenth century*, appeared a curious work, entitled, *Fruit-walls improved by inclining them to the Horizon*, by N. Facio de Doulier, F. R. S.
This work incurred the censure of the practical authors of the day; but founded on correct mathematical principles, it attracted the attention of the learned, and of some noblemen. Among the latter was the Duke of Rutland, and the failure of the trial of one of these walls, led to the earliest example which we have been able to discover of forcing grapes in England. This, Lawrence and Switzer agree, was successfully accomplished at Belvoir Castle, in 1705. Switzer published the first plans of forcing-houses, with directions for forcing generally, in his *Fruit Gardener*, in 1717.

411. *The nineteenth century has commenced by extraordinary efforts in horticulture.* The culture of exotic fruits and forcing has been greatly extended, and while in the middle of the eighteenth century scarcely a forcing-house was met with, excepting near the metropolis; there is now hardly a garden in the most remote county, or a citizen's potager, without one or more of them. The public markets, especially those of the metropolis, are amply supplied with forced productions, and far better pines, grapes, and melons are grown in Britain than in any other part of the world.

412. *The London Horticultural Society,* established in 1805, has made astonishing exertions in procuring and disseminating fruits, culinary vegetables, and horticultural knowledge, and has succeeded in rendering the subject popular among the higher classes, and in stimulating to powerful exertion the commercial and serving gardeners. A great and lasting benefit conferred on gardening by this society is the publicity and illustration which they have given by their transactions to the physiological discoveries of Knight, who has unquestionably thrown more light on the nature of vegetation than any other man, at least in this country.

**SUBJECT 2. Gardening in Scotland, in respect to its horticultural Productions.**

413. *The earliest Scottish horticulturists.* Chalmers remarks, were the abbots; and their orchards are still apparent to the eyes of antiquaries, while their gardens can now be traced only in the chartularies. A number of examples of gardens and orchards are mentioned in writings of the twelfth and thirteenth centuries: and even at this day, Mr. Neil observes, "several excellent kinds of fruits, chiefly apples and pears, are to be found existing in gardens, near old abbeys and monasteries. That such fruits were introduced by ecclesiastics cannot admit of a doubt. The Arbroath oslin, which seems nearly allied to the burr knot apple of England, may be taken as an instance; that apple having been long known all round the abbey of Aberbrothwick, in Forfarshire; and tradition uniformly ascribing its introduction to the monks.—The great care bestowed on the culture of fruits, and of some culinary herbs, by the clergy and nobility, could not fail to excite, in some degree, the curiosity and the attention of the inhabitants in general; and it may, perhaps, be said that the first impulse has scarcely spent its force; for it is thus but comparatively a short time (four or five centuries) since the cultivation of apples, pears, cherries, gooseberries, and currants, and many of the common kitchen-vegetables, were introduced into this country."  

414. *About the beginning of the eighteenth century,* the best garden in Scotland was that of J. Justice, at Crichton, near Edinburgh. From the year 1760 to 1785, that of Moredun claimed the priority. Moredun garden was managed by William Kyle, author of a work on forcing peaches and vines; and Dr. Duncan informs us, that the late Baron Moncrieff, its proprietor, "used to boast, that from his own garden, within a few miles of Edinburgh, he could, by the aid of glass, coals, and a good gardener, match any country in Europe, in peaches, grapes, pines, and every other fine fruit, excepting apples and pears;" these he acknowledged were grown better in the open air in England, and the north of France. (*Discourse to Caled. Hort. Soc.* 1814.) It is observed, in another of Dr. Duncan's discourses to this society, that in 1817, on the 10th of June, a bunch of Hamburg grapes was presented, weighing four pounds, the berries beautiful and large. "In June, it is added, such grapes could not be obtained at any price, either in France, Spain, or Italy." These facts are decisive proofs of the perfection to which horticulture has attained in Scotland, in spite of many disadvantages of soil, climate, and pecuniary circumstances.

415. *The Scotch authors* on this department of gardening are not numerous. The first was Reid in the beginning, and the best, Justice, about the middle of the eighteenth century. In the nineteenth century, Nicol's works appeared, and a variety of other writers in the memoirs of the Caledonian Horticultural Society.

416. *The nineteenth century promises greatly to increase the reputation of Scotland for gardeners and gardening,* not only from the general improvement in consequence of the increase of wealth and refinement among the employers and patrons of the art; but from the stimulus of the Caledonian Horticultural Society, which, by well devised competitive exhibitions and premiums, has excited a most laudable emulation among practical gardeners of every class.
Subsect. 3. Gardening in Ireland, in respect to its horticultural Productions.

417. As far as respects hardy fruits and culinary vegetables, the gardens of the principal proprietors in Ireland may be considered as approaching to those of Scotland or England; as they are generally managed by gardeners of these countries; but, in respect to exotic productions, Irish gardens are far behind those of the sister kingdoms. Indeed, it is only within the last fifteen years that it has become the practice to build hot-houses of any description in that country; and the number of these is still very limited. The first forcing-house was erected in the Blessington gardens. The gardens of the minor nobility and gentry of Ireland are poor in horticultural productions; many content themselves with cabbages and potatoes, and perhaps a few pears, onions, and apples.

Sect. IV. British Gardening, in respect to the planting of Timber-trees and Hedges.

418. The British Isles were well stocked with timber when comparatively unpopulated with men. As population increased, culture extended itself, and forests were encroached on or eradicated, to make room for the plough or the scythe. History, as far as it goes, bears witness to this state of things in England, Scotland, and Ireland.

Subsect. 1. Gardening in England, in respect to the planting of Timber-trees and Hedges.

419. The woods of England were so numerous and extensive when Domesday-book was compiled, as to be valued, not by the quantity of timber, but by the number of swine which the acorns and mast could maintain. Four hundred years after this, in the time of Edward IV., an eminent writer says, that England was then a well timbered country.

420. Till the beginning of the seventeenth century, the subject of planting for timber and fuel, seems not to have attracted much attention as an important part of the rural economy of England. Sir John Norden, in his Surveyor’s Dialogue, published in 1607, notices the subject; as had been done before by Benose, in 1538, and Fitzherbert, in 1559. In 1612 was published, Of planting and preserving of Timber and Fuel, an old Thrift newly reviced, by R. C.; and in the following year, Directions for planting of Timber and Fire Wood, by Arthur Standish. Planting for timber and copse is noticed in Googe’s Husbandry, published in 1614, and is the express subject of Manwood’s Treatise on Forests, and their Original and Beginning, published in 1615; and of Rathbone’s Surveyor, in 1616. It is singular that so many books on this subject should have been published so near together at so early a period. The reason seems to be, as professor Martyn has observed, that a material attack was made on the forest-trees in the 27th year of the reign of Henry VIII., when that monarch seized on the church-lands; and from this time the consumption of oak-timber was continually increasing, not only in consequence of the extension of commerce, and of great additions to the royal navy, but because it was made more use of in building houses. This alarmed both government and individuals. Holinshead, who lived in the reign of Elizabeth, says, that in times past men were contented to live in houses built of sallow, willow, &c.; so that the use of oak was, in a manner, dedicated wholly unto churches, religious houses, princes’ palaces, navigation, &c.; but now nothing but oak is any where regarded.

In the reign of James I., it appears that there was great store of timber, more than proportioned to the demand. For on a survey of the royal forests, &c. in 1608, we find that a great part of what was then intended to be sold, remained a considerable time undisposed of.

During the civil war, in the time of Charles I., and all the time of the interregnum, the royal forests, as well as the woods of the nobility and gentry, suffered so much, that many extensive forests had, in a few years, hardly any memorial left of their existence but their names. This loss would not have operated so severely, had the principal nobility and gentry been as solicitous to plant with judgment, as to cut down their woods.

The publication of Evelyn’s Sylva, in 1664, raised a great spirit of planting, and created a new era in this as in other branches of gardening. In his dedication to Charles II., in 1663, he observes, that he need not acquaint the king with many millions of timber-trees have been planted in his dominions, at the instigation, and by the sole direction of that work. The government at that time, alarmed by the devastation which had been committed during the civil war, gave great attention to the increase and preservation of timber in the royal forests.

421. Tree-nurseries were established during the seventeenth century. Young trees, the early authors inform us, were procured from the natural forests and copses, where they were self-sown; but about the beginning of the seventeenth century, public nursery-gardens were formed, originally for fruit-trees; but towards the end, nurserymen, as we learn from Switzer and Cooke, began to raise forest-trees and hedge-plants from seeds. The first nursery we hear of was that of Corbett, at Twickenham, mentioned by Ben Jonson, and the next of consequence that of London and Wise, at Brompton Park, already mentioned, and still continued as a nursery.

422. During the eighteenth century, especially in the latter part, planting proceeded rapidly. The Society of Arts, &c. established in 1758, have greatly contributed, by their honorary and pecuniary rewards, to restore the spirit for planting. The republication of Evelyn’s Sylva, in a splendid manner, by Dr. Hunter, and subsequently of
different works by Kennedy, Young, the Bishop of Llandaff, Marshall, Pontey, and others, has doubtless contributed to that desirable end; and the result is, that many thousand acres of waste lands have been planted with timber-trees, independently of demesne-plantations, and such as have been made for shelter or effect.

423. The nineteenth century has commenced with a much more scientific mode of planting and managing trees than formerly existed. Excellent modes of pruning have been pointed out and practised by Pontey, which will render future plantations much more valuable than where this operation and thinning have been so generally neglected as hitherto.

424. At what time hedges were introduced into England is uncertain. They would probably be first exhibited in the gardens of the Roman governors, and afterwards re-appear in those of the monks. From these examples, from the Roman authors on husbandry, or more probably from the suggestion of travellers who had seen them abroad, they would be introduced in rural economy. Marshal conjectures, that clearing out patches in the woods for aration, and leaving strips of bushes between them, may have given the first idea of a hedge, and this supposition is rendered more plausible, from the circumstance of some of the oldest hedges occupying so much space, and consisting of a variety of plants. However originated, they did not come into general use in laying out farms till after the Flemish husbandry was introduced in Norfolk about the end of the seventeenth century. (Kent's Hints, &c.) So rapidly have they increased since that period, that at the end of the eighteenth century they had entirely changed the face of the country. In the time of George I. almost every tract of country in England might have been said to consist of four distinct parts or kinds of scenery: 1. The houses of the proprietors, and their parks and gardens, and the adjoining village, containing their farmers and labourers; 2. The common field or intercommunable lands in aration; 3. The common pasture, or waste untouched by the plough; and, 4. The scattered or circumscribing forest containing a mass of timber or copse. But at present these fundamental features are mixed and variously grouped, and the general face of the country presents one continual scene of garden-like woodiness, interspersed with buildings and cultivated fields, unequalled in the world.

The oldest enclosures in England are in Kent and Essex, and seem to have been formed of hawthorn, sloe, crab, hazel, dogwood, &c. taken from the copses, and planted promiscuously; but now almost all field or fenc-hedges are formed of single or double rows of hawthorn, with or without trees, planted at regular distances to shoot up for timber.

Subsect. 2. Gardening in Scotland, in respect to the planting of Timber-trees and Hedges.

425. Scotland in ancient times was clothed with extensive tracts of wood. (Graham, in Gen. Rep. of Scot. vol. ii.) By various operations carried on by the land of Nature and of man, this clothing has been in a great measure destroyed. The attempts to restore it by planting timber, however, appear to be of recent origin. Dr. Walker seems to be of opinion, that the elder (Sambucus nigra) was the first barren tree planted in Scotland; and that the plane or sycamore was the next. The wood of the former was in much request for making arrows. "A few chestnuts and beeches," he adds, "were first planted in gardens, not long before the middle of the seventeenth century, some of which have remained to our times." Notwithstanding this high authority, however, there seems to be good reason to conclude, that some trees which still exist were planted before the Reformation; they appear to have been introduced by the monks, being found for the most part in ecclesiastical establishments. Such are the Spanish chestnuts, the most of which are still in a thriving condition in the island of Inchmahome, in the lake of Monteith, in Perthshire, where there was a priory built by David I. Some of these chestnut-trees measure within a few inches of eighteen feet in circumference, at six feet from the ground. They are probably three hundred years old, or upwards. There are planted oaks at Buchanan, which are apparently of the same age.

426. The father of planting in Scotland, according to Dr. Walker, was Thomas, Earl of Haddington, having begun to plant Binning-wood, which is now of great extent and value, in 1705. But it is stated on an authority almost approaching to certainty, that the fine timber in the lawn at Callender House, in Stirlingshire, was planted by the Earl of Linlithgow and Callender, who had accompanied Charles II. in his exile, upon his return from the continent after the Restoration. This timber is remarkable, not only for its size, but for its quantity. Planting for timber became very general in Scotland between the years 1730 and 1760, by the exertions and example of Archibald, Duke of Argyle, the Duke of Athol, the Earls of Bute, Loudon, Hyndford, and Panmure, Sir James Nasmyth, Sir Archibald Grant, Fletcher of Selltoun, and others. It is well ascertained that Sir Archibald Grant began to plant in 1719.

427. A great stimulus to planting in Scotland was given by the Essays of Dr. Anderson, published in 1784, in which the value of the larch-tree and the progress it had made at Dunkeld, since planted there in 1741. were pointed out. The examples and
writings of Lord Kames also contributed to bring this, and every description of rural improvement into repute; but the high price of timber during the war produced the most sensible effect as to planting.

428. The two first tree-nurseries in Scotland were established at Edinburgh, about the beginning of the eighteenth century, by Malcolm, at the Water Gate, and Gordon, at the Fountain Bridge. To these succeeded a considerable one by Anderson and Leslie, about 1770. Leslie contributed to render the larch popular, and was the first nurseryman who ventured to erect a greenhouse. Since this period, tree-nurseries are nearly as common in Scotland as in England.

429. Hedges were introduced to Scotland by some officers in Cromwell's army about the middle of the seventeenth century. The first were planted at Inch Buckling Brae, in East Lothian, and at the head of Loch Tay, in Perthshire. The former hedge was in existence in 1804, and then consisted of a single row of old hawthorns. They are now general in all the low and tolerably fertile and sheltered parts of the country; contributing with the plantations to ameliorate the climate, and greatly to improve the scenery.

SUBSECT. 3. Gardening in Ireland, in respect to the planting of Timber-trees and Hedges.

430. Trees appear to have covered Ireland in former times. "Though in every part of Ireland, in which I have been," observes A. Young, in 1777, (Tour, vol. ii. 2d edit.) "one hundred contiguous acres are not to be found without evident signs that they were once wood, at least very well wooded; yet now the greatest part of the kingdom exhibits a naked, bleak, dreary view, for want of wood, which has been destroyed for a century past with the most careless prodigality, and still continues to be cut and wasted. The woods yet remaining are what in England would be called copses. The gentlemen in that country are much too apt to think they have got timber, when in fact they have got nothing but fine large copse-wood." Shaw Mason, in a Statistical Survey of Ireland, lately published, says there were natural woods in some places in James II.'s time; but he produces very few instances, of artificial plantations of full growth, and none of older date than the middle of the seventeenth century, when it appears, that through the instigation of Blythe and other officers in Cromwell's army, some gentlemen began to plant and improve. The late Lord Chief Baron Foster was the greatest planter when A. Young visited Ireland, and his lordship informed the tourist that the great spirit for this sort of improvement began about 1749 and 1750.

431. Hedges, as fences, were probably, as in Scotland, introduced by the officers of Cromwell's army.

SECT. V. British Gardening, as empirically practised.

432. The use of gardens, is perhaps more general in England and Scotland than in any other country, if we except Holland. The laborious journeyman-mechanic, whose residence, in large cities, is often in the air, rather than on the earth, decorates his garret-window with a garden of pots. The debtor deprived of personal liberty, and the pauper in the work-house, divested of all property in external things, and without any fixed object on which to place their affections, sometimes resort to this symbol of territorial appropriation and enjoyment. So natural it is for all to fancy they have an inherent right in the soil; and so necessary to happiness to exercise the affections, by having some object on which to place them.

433. Almost every cottage in England has its appendant garden, larger or smaller, and slovenly or neatly managed, according to circumstances. In the best districts of England, the principal oleraceous vegetables, some salads, herbs, flowers, and fruits are cultivated; and in the remote parts of Scotland, at least potatoes and borecoles are planted. Tradesmen and operative manufacturers, who have a permanent interest in their cottages, have generally the best cottage-gardens; and many of them, especially at Norwich, Manchester, and Paisley, excel in the culture of florists' flowers.

434. The gardens of farmers are larger, but seldom better managed than those of the common cottagers, and not often so well as those of the operative manufacturers in England. They are best managed in Kept and in East Lothian.

435. The gardens and grounds of citizens, who have country-houses, may be, in size, from an eighth of an acre to a hundred acres or upwards. Such a latitude, it may easily be conceived, admits of great variety of kitchen-gardens, hot-houses, flower-gardens, and pleasure-grounds. They are, in general, the best managed gardens in Britain, and constitute the principal scenery, and the greatest ornament of the neighbourhood of every large town. Those round the Metropolis, Liverpool, and Edinburgh are pre-eminent.

436. The gardens of independent gentlemen of middling fortune vary considerably in dimension. Few of the kitchen-gardens are under an acre, the flower-garden may contain a fourth or a third of an acre, and the pleasure-ground from three to ten or
twelve acres. The lawn or park varies from thirty or forty to three or four hundred acres. The whole is in general respectively kept up, though there are many exceptions arising from want of taste, of income, or engagements in other pursuits on the part of the proprietor; or restricted means, slovenliness, and want of taste and skill in the head gardener. These gardens abound in every part of every district of Britain, in proportion to the agricultural population.

437. The first-rate gardens of Britain belong chiefly to the extensive land-holders; but in part also to wealthy commercial men. The kitchen-gardens of this class may include from three to twelve acres, the flower-garden from two to ten acres, the pleasure-ground from twenty to one hundred acres, and the park from five hundred to five thousand acres. Excepting in the cases of minority, absence of the family, or pecuniary embarrassments, these gardens are kept up in good style. They are managed by intelligent head gardeners, with assistants for the different departments, and apprentices and journeymen as operatives. A few of such residences are to be found in almost every county of England, in most of those in Scotland, and occasionally in Ireland.

438. The royal gardens of England cannot be greatly commended; they are in no respect adequate to the dignity of the kingly office. That at Kew has been already mentioned as containing a good collection of plants; but neither this nor any of the other royal gardens are at all kept in order as they ought to be, not on account of want of skill in the royal gardeners, but for want of support from their employers.

439. Gardens for public recreation are not very common in Britain; but of late a considerable specimen has been formed at London in the Regent's Park, an extensive equestrian promenade, and one at Edinburgh on the Calton Hill, of singular variety of prospect. There are also squares and other walks, and equestrian promenades, in the metropolis, and other large towns; but in respect to this class of gardens, they are much less in use in Britain than on the continent, for Britons are comparatively domestic and solitary animals.

440. Of gardens for public instruction, there are botanic gardens attached to the principal universities and experimental gardens belonging to the London and Edinburgh horticultural societies.

441. Commercial gardens are very numerous in Britain, arising from the number, magnitude, and wealth of her cities being much greater in proportion to the territorial extent of the country than in any other kingdom. In general, they have been originated by head gardeners, who have given up private servitude.

442. Market-gardens and orchards are numerous, especially round the metropolis, and their productions are unequalled, or at least not surpassed by any gardens in the world, public or private. Forcing is carried on extensively in these gardens, and the pine cultivated in abundance, and to great perfection. Their produce is daily exposed in different markets and shops; so that every citizen of London may, throughout the year, purchase the same luxuries as the king or as the most wealthy proprietors have furnished from their own gardens, and obtain for a few shillings what the wealth of Creesus could not procure in any other country! a striking proof of what commerce will effect for the industrious. Some gardens are devoted to the raising of garden-seeds for the seed-merchants, and others, to the growing of herbs and flowers for the chemist or distiller.

443. There are florists' gardens, where plants are forced so as to furnish roses and other flowers of summer in mid-winter. The tradesman's wife may thus at pleasure procure a drawing-room garden equal to that of her sovereign, and superior to that of all the kings and nobles on the rest of the globe.

444. Of nursery-gardens for stocking and forming new gardens and plantations, and repairing or increasing the stock of old ones, there are a number in which a very considerable capital is embarked. These have greatly increased with the increasing spirit for planting, and other branches of gardening. The principal are near the metropolis; but they are to be found in most districts, originated in almost every case by head gardeners, whose capital consists of the savings made during their servitude.

445. The operative part of gardening is carried on by labourers, apprentices, journeymen, and masters.

The labourers are women for weeding, gathering some descriptions of crops, and other light works: and men for assisting in the heavier operations in extraordinary seasons. The permanent substantial operatives are the apprentices and journeymen; the former are indentured generally for three years, at the expiration of which they become journeymen, and after a few years' practice in that capacity, in different gardens, they are considered qualified for being masters, or taking the charge of villa, private, or first-rate gardens according to their capacity, education, and assiduity, and the class of gardens in which they have studied and practised. Formerly there were lodges, or societies of gardeners, and a sort of mystic institution and pass-word kept up, like those of the German gardeners and masons; but within the last fifty years this has been in most places given up. The use of books, and the general progress of society, render such institutions useless in point of knowledge and hospitality, and injurious politically, or in respect to the market-value of labor. (Preston's History of Masonry.)
The head gardeners of this country are universally allowed to be the most intelligent and trust-worthy part of the operatives of any branch of rural economy, and the most faithful and ingenious of those who constitute the serving establishment of a country residence. Those of Scotland are by many preferred, chiefly, perhaps, from their having been better educated in their youth, and more accustomed to frugality and labor. Scotland, Neil observes, "has long been famous for producing professional gardeners; perhaps more so than any other country, unless we except Holland, about a century ago. At present, not only Great Britain, but Poland and Russia are supplied from Scotland; and the numbers of an inferior class to be found in every part of England and Ireland, is quite astonishing." (Gen. Rep. &c. chap. ii.) Lord Gardenstone (Travelling Memorandum, 1790) says, that in every country in Europe, he found gardeners more sober, industrious, and intelligent than other men of a like condition in Society.

446. The use of gardens in Ireland is of a very limited description, and the gardens there, of all the classes, are greatly inferior to the corresponding classes in Britain. A few exceptions may be made in favor of the Dublin botanic gardens, and those of one or two wealthy citizens and extensive proprietors; but the cottage-gardens, in many districts, contain nothing besides potatoes; and potatoes are the chief ingredients in the gardens of private gentlemen. Parnel, Wakefield, and Curwen, have ably shown that till wheaten bread and meat take place of these roots, no great improvement can be expected among the lower classes of Ireland.

447. The artists or architects of gardens, in Britain, are of three classes. First, head gardeners who have laid out the whole, or part of a residence, under some professor, and who commence artist or ground workmen, as this class is generally denominated, as a source of independence. Such was Hitt, Brown, &c. Secondly, architects who have devoted themselves chiefly to country-buildings, and thus acquiring some knowledge of country-matters, and the effects of scenery, combine with building, the laying out of grounds, depending for the execution of their ideas on the practical knowledge of the gardener, pro tempore. This class are commonly called ground-architects. Such was Kent. Thirdly, artists who have been educated and apprenticed, or otherwise brought up entirely, or chiefly for that profession. These are often called landscape-gardeners, but the term is obviously of too limited application, as it refers only to one branch of the art. Such was Bridgeman, Eames, &c.

Sect. VI. British Gardening, as a Science, and as to the Authors it has produced.

448. Those superstitious observances attendant on a rude state of society, retained their ground in British gardening till the end of the seventeenth century. Meager, Mascal, Worlidge, and the authors who preceded them, regulate the performance of horticultural operations by the age of the moon. Turnips or onions, according to these authors, sown when the moon is full, will not bulb but send up flower-stalks; and fruit-trees, planted or grafted at that season, will have their period of bearing greatly retarded. A weak tree is to be pruned in the increase, and a strong tree in the wane of the moon. Quintinnye seems to have been the first to oppose this doctrine in France, and through Evelyn's translation of his Complete Gardener, he seems to have overruled it also in England. "I solemnly declare," he says, "that after a diligent observation of the moon's changes for thirty years together, and an enquiry whether they had any influence in gardening, the affirmative of which has been so long established among us, I perceived that it was no weightier than old wives' tales, and that it had been advanced by unexperienced gardeners. I have, therefore, followed what appeared most reasonable, and rejected what was otherwise; in short, graft in what time of the moon you please, if your graft be good, and grafted on a proper stock, provided you do it like an artist, you will be sure to succeed. In the same manner sow what sorts of grain you please, and plant as you please, in any quarter of the moon, I'll answer for your success, the first and last day of the moon being equally favorable."

Quintinnye not only removed ancient prejudices, but introduced more rational principles of pruning than had before been offered. Switzer says, he first made it known that a transplanted tree could not grow till it made fresh fibres, and that therefore the old ones, when dried up, might be cut off.

449. The influence of Bacon's writings produced the decline and fall of astrology, in the beginning of the eighteenth century. A different mode of studying the sciences was adopted. Vegetable physiology and chemistry, the first a new science, and the latter degraded under the name of alchemy, began to be studied, and the influence of this dawn of intellectual day was felt even in agriculture and gardening.

450. The practice of forcing fruits and flowers, which became general about the middle of the century, led gardeners to reflect on the science of their art, by bringing more effectually into notice the specific influence of light, heat, air, water, and other agents of vegetation. The elementary botanical works published about the same time, by diffusing the doctrines of Linnaeus, co-operated; as did the various horticultural writers of this century, especially Miller, Bradley, and Hill, and subsequently Home, Anderson, and others.

451. The increasing culture of exotics, Doctor Pulteney observes, "from the beginning of the eighteenth century, and the greater diffusion of taste for the elegancies and luxuries of the stove and green-house, naturally tended to raise up a spirit of improve-
ment and real science in the art of culture. To preserve far-fetched varieties, it became necessary to scrutinize into the true principles of the art, which ultimately must depend on the knowledge of the climate of such plant, and the soil in which it flourishes in that climate. Under the influence of such men as Sloane, the Sherrards, and other great encouragers of science, gardeners acquired botanical knowledge, and were excited to greater exertion in their art."

452. The increased zeal for planting, and more careful attendance to the pruning of trees, tended to throw light on the subject of vegetable wounds, and their analogy with those of animals, as to the modes of healing, though the French laugh at our ignorance on this subject (Cours d'Agr. art. Plais.) at the close of the eighteenth century.

453. But the science of horticulture received its greatest improvement from Knight, the enlightened president of the Horticultural Society. The first of this philosopher's writings will be found in the Philosophical Transactions for 1795, entitled Observations on the Grafting of Trees. In the same Transactions for 1801 and 1803, are contained his ingenious papers on the fecundation of fruits, and on the sap of trees. Subsequent volumes contain other important papers; and a great number in which science and art are combined, in a manner tending directly to enlighten and instruct the practical gardener, will be found in the Transactions of the Horticultural Society. Through the influence of this author and that society, over which he is so worthy to preside, we see commenced an important era in the horticulture of this country, an era rendered peculiarly valuable, as transferring the discoveries of science immediately to art, and rendering them available by practitioners. How great may be its influence, on the comforts and luxuries of the table, it is impossible to foresee. The introduction and distribution of better sorts of the common hardy fruits and culinary plants, will tend immediately to the benefit of the humbler classes of society; and by increasing a little the size, and encouraging the culture, both ornamental and useful, of cottage-gardens, the attachment of this class to their homes, and consequently their interest in the country, will be increased. Even agriculture will derive advantages, of which, as an example, may be adduced the result of pinching off the blossoms of the potatoe, which, by leaving more nourishment for the root, will increase the produce (according to Knight's estimate) at least one ton per acre. (Hort. Tr. i. 190. Treatise on the Apple and Pear.)

454. Gardening, as an art of design and taste, may be said to have been conducted mechanically, and copied from precedents, like civil architecture, till the middle of the eighteenth century; but at this time the writings of Addison, Pope, Shenstone, and G. Mason appeared; and in these, and especially in the Observations on Modern Gardening, by Wheatley, are laid down unalterable principles for the imitation of nature in the arrangement of gardening scenery. The science of this department of the art may therefore be considered as completely ascertained; but it will probably be long before it be appropriated by gardeners, and applied in the exercise of the art as a trade. A somewhat better education in youth, and more leisure for reading in the periods usually devoted to constant bodily labor, will effect this change; and its influence on the beauty of the scenery of country-residences, and on the face of the country at large, would be such as cannot be contemplated without a feeling of enthusiastic admiration. If this taste were once duly valued and paid for by those whose wealth enables them to employ first-rate gardeners, it would soon be produced. But the taste of our nobility does not, in general, take this turn, otherwise many of them would display a very different style of scenery around their mansions.

455. Britain has produced more original authors on gardening than any other country. It may be sufficient here to mention, in the horticultural department, Justice, Miller, and Abercrombie. In ornamental gardening, Parkinson and Madocks; in planting, Evelyn and Nicol; and in landscape-gardening, G. Mason and Wheatley.

CHAP. V.

Of the present State of Gardening in Ultra-European Countries.

456. The gardens of the old continents are either original, or borrowed from modern Europe. With the exception of China, the gardens of every other country in Asia, Africa, and America, may be comprised under two heads. The aboriginal gardens displaying little design or culture, excepting in the gardens of rulers or chiefs; and the gardens of European settlers displaying something of the design and culture of their respective countries. Thus the gardening of the interior of Asia, like the manners of the inhabitants, is the same, or nearly the same, now, that it was 3000 years ago; that of North America is British; and that of almost all the commercial cities in the world, ex-
cepting those of China, is European, and generally either Dutch, French, or English. We shall notice slightly, 1st, The aboriginal gardening of modern Persia and India; 2d, Of China; 3d, The state of gardening in North America; and 4th, In the British colonies and other settlements abroad.

457. The outlines of a Jewish garden, nearly 3000 years ago, coincide with the gardens formed in the same countries at the present day. Maundrel in the fourteenth century, Russel in the seventeenth, Chardin in the eighteenth, and Morier in the nineteenth centuries, enumerate the same trees and plants mentioned by Moses, Diodorus, and Herodotus, without any additions. The same elevation of site for the palace (fig. 33.) the same terraces in front of it; and the same walls and towers surrounding the whole for security, still prevail as in the time of Solomon and his successors. Maundrel describes the garden of the Emir Facardine, at Beroot, as a large quadrangular spot of ground divided into sixteen lesser squares, four in a row, with walks between them, and planted with citron-trees. Each of the lesser squares was bordered with stone, and in the stone-work were troughs, very artificially contrived for conveying the water all over the garden, there being little outlets cut at every tree, for the stream as it passed by to flow out and water it. On the east side were two terrace-walks, rising one above the other, each having an ascent to it of twelve steps. At the north end they led into booths and summer-houses, and other apartments very delightful. (Travels from Aleppo to Jerusalem, p. 40.)

458. The gardens of Damascus are described by Egmont and Heyman as perfect paradieses, being watered with copious streams from Lebanon; and in the Account of the Ruins of Balheek, the streams are said to be derived from Lebanon and Anti-Lebanus, and the shades of the palms and elms are described as exquisite in that burning climate. The time of the singing of birds is mentioned in Solomon's Song as a season of great pleasure, and then as now, they no doubt constituted a material article in fine gardens. Russel observes, that "in Syria there are abundance of nightingales, which not only afford much pleasure by their songs in the gardens, but are also kept tame in the houses, and let out at a small rate to divert such as choose it in the spring, so that no entertainments are made in this season without a concert of these birds." (Natural Hist. of Aleppo, p. 71.)

459. The gardens of the Persians, observes Sir John Chardin, in 1732, "consist commonly of a grand alley or straight avenue in the centre planted with planes (the zinzar, or chenar of the east), which divides the garden into two parts. There is a basin of water in the middle, proportionate to the garden, and two other lesser ones on the two sides. The space between them is sown with a mixture of flowers in natural confusion, and planted with fruit-trees and roses, and this is the whole of the plan and execution. They know nothing of parterres and cabinets of verdure, labyrinths, terraces, and such other ornaments of our gardens. The reason of which is, that the Persians do not walk in their gardens as we do, but content themselves with having the view of them, and breathing the fresh air. For this purpose they seat themselves in some part of the garden as soon as they come into it, and remain there till they go out." According to the same author, the most eastern part of Persia, Hyrcania, is one entire and continued parterre from September to the end of April. "All the country is covered with flowers, and this is also the best season for fruits, since in the other months they cannot support the heat and unhealthy state of the air. Towards Media and the northern frontiers of Arabia, the fields produce of themselves tulips, anemones, single ranunculus of the most beautiful red, and crown imperials. In other places, as around Isphahan, jonquils are wild and flower all the winter. In the season of narcissus,
seven or eight sorts spring up among lilies (*Lilium*), lily of the valley, violets of all colors, gilly-flowers, and jessamines, all of an odor and beauty far surpassing those of Europe. But nothing can be more beautiful than the peach-trees, so completely covered with flowers as to obstruct the view through their branches." Morier mentions the garden of Azar Gerib, in Isphahan, as extending a mile in length, and being formed on a declivity divided into twelve terraces, supported by walls, each terrace divided into a great number of squares. This garden is devoted to the culture of the most esteemed Persian fruits. The neighbourhood of Bushire was formerly famous for its gardens; but Morier informs us, "that in the whole territory of Bushire at this day, there are only a few cotton-bushes (*Acacia Julibrissin*); here and there date-trees; now and then a konar-tree (a palm), with water-melons, beringauts (gourds), and cucumbers." These date-trees, the towers, and the presence of camel-drivers, gave this town, when Morier saw it, a truly Persian appearance. (Fig. 32.)

460. *The gardens of Kerim Khan* are thus described by Morier: "An immense wall of the nearest construction encloses a square tract of land, which is laid out into walks shaded by cypress and cheur (*Platania*), and watered by a variety of marble canals, and small artificial cascades. Over the entrance, which is a lofty and arched passage, is built a pleasure-house. In the centre of the garden is another of the principal pleasure-houses. There is a basin in the middle of the principal room, where a fountain plays and refreshes the air, &c. The whole soil of this garden is artificial, having been exca

461. *The gardens of the chief of India, now or lately existing, are of the same general character as those of Persia.* "In the gardens belonging to the Mahomedan princes, which in some parts of India were made at a very great expense, a separate piece of ground was usually allotted for each kind of plant, the whole being divided into square plots, separated by walks. Thus one plot was filled with rose-trees, another with pomegranates, &c. The gardens of this sort, most celebrated in India, were those of Bengal and Delhi. The former, belonging to Tippoo, were made by him and his father, Hyder Ali. As Bengalore is very much elevated above the sea, it enjoys a temperate climate; and in the royal gardens there were seen not only the trees of the country, but also the cypress, vine, apple, pear, and peach; both the latter produced fruit. Strawberries were likewise raised, and oaks and pine-trees, brought from the Cape of Good Hope, flourished. Some magnificent palaces and walled gardens (Fig. 33.) are mentioned by Morier and other oriental travellers; but all agree in representing their interior in a state of neglect.

462. *The gardens of Kalmor*, near Delhi, which were made in the beginning of the seventeenth century by the Emperor Shaw Jehan, are said to have cost 1,000,000£ sterling, and were about a mile in circumference. They were surrounded by a high brick wall; but the whole are now in ruins." (Edin. Encyc. art. India, p. 87.)

463. Of the royal gardens of Shaw Lecom, near Lahore, a city of Hindostan, some account is given in the Journal of the Royal Institution for July, 1820. "They differ," says the writer, "from the indigeneous royal gardens generally found in India, in belonging to the class of hanging-gardens." Their length is about 500 yards, and their breadth about 140. They consist of three terraces watered by a stream brought upwards of sixty miles, and irrigating the country through which it passes. The only thing worthy of notice is the use of this water in cascades for cooling the air. There are large trees, including the apple, pear, and mango, a border and island of flowers, among
which the narcissus abounds. Captain Benj. Blake, who describes these gardens, in making excursions in the neighbourhood, "stumbled, as it were, upon a most magnifi-
cent mausoleum, round which was a walled garden of orange and pomegranate trees."

464. The gardens of the islands of Japan partake of the same general character as those of Persia and Hindostan. According to Kämpfer, they display little of taste in design, but are full of the finest flowers and fruits. "Such," he says, "is the beauty of the flowers which ornament the hills, the fields, and the forests, that the country may even dispute the preference in this point with Persia. They transplant the most beautiful of their wild flowers into the gardens, where they improve them by culture. Colors are the grand beauties desired both in plants and trees. Chestnut-trees, lemons, oranges, citrons and peaches, apricots and plums, abound. The sloe, or wild plum, is cultivated on account of its flowers, which by culture acquire the size of a double rose, and are so abundant that they cover the whole tree with a snowy surface speckled with blood. These are the finest of their ornaments, they are planted in preference around their temples: and they are also cultivated in pots or boxes for private houses, as oranges are in Europe. They plant the summits of the mountains, and both sides of the public roads, with long rows of fir-trees and cypress, which are common in the country. They even ornament sandy places and deserts by plantations; and there exists a law in this island, that no one can cut down a tree without permission of the magistrate of the place, and even when he obtains permission, must replace it immediately by another."

465. The gardens of the different African seaports on the Mediterranean, such as Tangier, Algier, Tunis, Tripoli, &c. have the same general character as those of Persia; but inferior in proportion to the degraded state of society in these comparatively barbarous places. The author of a Ten Years' residence in Tripoli confirms the remarks of Chardin and Kämpfer, as to the carelessness with which art lends her aid to nature. "In their gardens the Moors form no walks; only an irregular path is left, which you trace by the side of white marble channels for irrigation. Their form is generally square, and they are enclosed by a wall, within which is planted a corresponding line of palm-trees. The whole is a mixture of beauty and desolation." (Narratives, &c. p. 52.)

466. The aboriginal horticulture of these countries consists chiefly in the culture of the native fruits, the variety of which is greater than that indigenous to any other country. The peach, the mango, all the palm tribe, and, in short, every fruit-tree cultivated in Persia and India by the natives, is raised from seed, the art of grafting or laying being unknown. Water is the grand desideratum of every description of culture in this country. Without it nothing can be done either in agriculture or gardening. It is brought from immense distances at great expense, and by very curious contrivances. One mode practised in Persia consists in forming subterranean channels at a considerable depth from the surface, by means of circular openings at certain distances, through which the excavated material is drawn up (fig. 34.); and the channels so formed, are known only to those who are acquainted with the country. These conduits are described by Polybius, a Greek author, who wrote in the second century before Christ; and Morier (Journey to Persia) found the description perfectly applicable in 1814. Doves' dung is in great request in Persia and Syria, for the culture of melons. Large pigeon-houses (fig. 35.) are built in many places, expressly to collect it. The melon is now, as it was

2500 years ago, one of the necessaries of life, and when the prophet Isaiah meant to convey an idea of the miseries of a famine, he foretold that a cab of doves' dung would be sold for a shekel of silver. The whole province of Syria was formerly famous for its horticultural productions, of which the bunch of grapes brought to Moses by his
spies (Mamb. xiii. 23.) is a proof; but it has been in a constant state of neglect since it came into the hands of the Turks, "who, of all nations," as Montesquieu observes, "are the most proper to enjoy large tracts of land with insignificance."

467. Trees and bushes appear to have been held in superstitious veneration in these countries as early as the time of Moses, of which the story of the burning bush may be adduced as a proof. There are many other instances mentioned in the Jewish writings, of attachment to trees, and especially to the oak and plane. Morier, Johnson, and Sir William Ouseley (Embassy, &c. vol. i.), describe the Persians as often worshipping under old trees in preference to their religious buildings. The chevar, or plane, is greatly preferred. On these trees the devotees sacrifice their old clothes by hanging them to their branches, and the trunks of favorite trees are commonly found studded with rusty nails and tatters. (Sir William Ouseley, App. 1819.) Groves of trees are equally revered in India, and are commonly found near the native temples and burial-places of the princes.

Sect. II. Chinese Gardening.

468. We know little of the gardening of China, notwithstanding all that has been written and asserted on the subject. It does not appear perfectly clear to us, that the difference between the gardens of Persia and India, and those of China, is so great as has been very generally asserted and believed. It is evident, that the Chinese study irregularity and imitate nature, in attempting to form rocks; but whether this imitation is carried to that extent in wood, water, and ground, and conducted on principles so refined as those given as Chinese by Sir William Chambers, appears very doubtful. With all this, it must be confessed, there is a distinctive difference between the Chinese style and every other, though to trace the line of demarcation does not appear practicable in the present state of our information on the subject.

469. One of the earliest accounts of Chinese gardens was given by Pere le Comte, who, as well as Du Halde, had resided in the country as a missionary. "The Chinese," observes Le Comte (Lettre vi.), "appear still more to neglect their gardens than their houses. They would consider it as a want of sense to occupy their grounds only in parterres, in cultivating flowers, and in forming alleys and thickets. The Chinese, who value order so little in their gardens, still consider them as sources of pleasure, and bestow some expense in their formation. They form grottoes, raise little hills, procure pieces of rocks, which they join together with the intention of imitating nature. If they can, besides these things, find enough of water to water their cabbages and legumes, they consider, that as to that material they have nothing more to desire, and content themselves with a well or a pond." Olof Toreen, a Swede, who visited China early in the eighteenth century, and has published an account of his travels, states, "that in the Chinese gardens are neither seen trees artificially cultivated, nor alleys, nor figured parterres of flowers; but a general confusion of the productions of verdant nature." (Voyage to Osbek, the East Indies and China, 8vo. 1761.)

470. The imperial gardens of China are described in the Lettres Edifiantes et Curieuses, &c. in a letter dated Pekin, 1743. It was translated by Spence, under the fictitious title of Sir Harry Beaumont, whom Lord Walpole describes as having "both taste and zeal for the present style;" and was published in Dodson's collection in 1761. These gardens are described to be of vast extent, containing 200 palaces, besides garden-buildings, mock towns, villages, all painted and varnished, artificial hills, valleys, lakes, and canals; serpentine bridges, covered by colonnades and resting-places, with a farm and fields, where his imperial majesty is accustomed to patronise rural industry, by putting his hand to the plough, or, as it has been otherwise expressed, "by playing at agriculture once a-year." Views of these gardens, taken by native artists for the Chinese missionaries, were sent to Paris about the middle of the eighteenth century, and engravings from them were published by permission of the court in 1788, in a work entitled Recueil des Plans des Jardins Chinois. We have examined the plan of the imperial gardens (fig. 36.) with the utmost care, but confess we can see nothing but a mass of buildings generally forming squares or courts, backed by peaked hills, and interspersed with pieces of water, sometimes evidently artificial, and at other times seemingly natural. The first jet-d'eau ever seen in China was formed in the imperial gardens by Pere Benoit, who went to Pekin as astronomer. The emperor was transported with it, and instead of astronomer, made the revered father the fountainier.

471. But the national taste of the Chinese in gardening must have had something characteristic in it, even to general observers; and this character seems to have been obscurely known in Europe from the verbal accounts of Chinese merchants or travellers, in the beginning of the seventeenth century. A proof of this is to be found in Sir William Temple's Essay, written about the middle of the seventeenth century. He informs us, that though he recommends regularity in gardens, yet, for any thing he
knows, there may be more beauty in such as are wholly irregular. "Something of this sort," he says, "I have seen in some places, but heard more of it from others, who have lived much among the Chinese." Referring to their studied irregularity, he adds, "When they find this sort of beauty in perfection, so as to hit the eye, they say it is sharaquivdi, an expression signifying fine or admirable." It appears from this passage, that the Chinese style had not only been known, but imitated in England, nearly a century previous to the publication of the Jesuit's Letters, and, at least, sixty years before Kent's time. Sir William Temple retired to East Sheen in 1680, and died in the year 1700.

472. Sir William Chambers's account of the Chinese style has given rise to much discussion. This author, afterwards surveyor-general, resided some time at Canton, and after returning to England, gave a detailed account of Chinese gardening; first in the appendix to his Designs of Chinese Buildings, &c. in 1757, and subsequently at greater length in his Dissertation on Oriental Gardening, in 1772, and commended, as G. Mason observes, by so good a judge as Gray. Sir William Chambers avows that his information is not derived entirely from personal examination, but chiefly from the conversation of a Chinese painter; and it has been very reasonably conjectured, that he has drawn, in some cases, on his own imagination, in order to enhance the reader's opinion of Chinese taste, with the laudable end of improving that of his own country. In his essay of 1757, which was published in French as well as English, and was soon translated, as Hirschfield informs us, into German, he says, "the Chinese taste in laying out gardens is good, and what we have for some time past been aiming at in England." With the exception of their formal and continual display of garden-buildings, and their attempts of raising characters, not only picturesque and pleasing, but also of horror, surprise, and enchantment, Sir William's directions, especially in his second work, will apply to the most improved conceptions of planting, and forming pieces of water, in the modern style; or, in other words, for creating scenery such as will always resemble, and often might be mistaken for that of nature. But whatever may be the merits of the Chinese in this art, it may reasonably be conjectured, that their taste for picturesque beauty is not so exactly conformable to European ideas on that subject as Sir William would lead us to believe. Their decorative scenes are carried to such an extreme, so encumbered with deceptions, and what we would not hesitate to consider puerilities, and there appears throughout so little reference to utility, that the more mature and chastened taste of Europeans cannot sympathise with them. Chinese taste is, indeed, altogether peculiar; it is undoubtedly perfectly natural to that people, and therefore not to be subjected to European criticism.

473. Lord Walpole's opinion of the Chinese gardens is that they "are as whimsically irregular as European gardens were formerly uniform and unvaried; nature in them is as much avoided as in those of our ancestors." In allusion to those of the emperor's palace, described in the Lettres Edifiantes, he says, "this pretty gaudy scene is the work
of caprice and whim; and when we reflect on their buildings, presents no image but that of unsubstantial tawdriness."

474. Lord Macartney's remarks on these gardens show, that at least picturesque scenes are seen from them. "The view," he says, "from one of the imperial gardens might be compared to that from the terrace at Lowther Castle." This view is altogether wild and romantic, and bounded by high uncultivated mountains, with no other buildings than one or two native cottages. In what degree of estimation such a view is there held does not, however, appear; it would be too much to conclude that, because it existed in that situation, it had been created or left on purpose, or was considered as eminently beautiful or desirable. "It is our excellence," observes his lordship, "to improve nature; that of a Chinese gardener to conquer her: his aim is to change every thing from what he found it. A waste he adorns with trees; a desert he waters with a river or a lake; and on a smooth flat are raised hills, hollowed out valleys, and placed all sorts of buildings."

475. The description of the gardens of Woo-yuen in Ellis's Journal of the late Embassy to China, 1818, is as follows: "We stopped opposite the gardens of Woo-yuen, which, after a little hesitation on the part of the mandarins, we were allowed to visit. Although now much neglected, they were interesting as a specimen of Chinese gardening. The Chinese are certainly good imitators of nature, and their piles of rocks are not liable to the same ridicule as some modern Gothic ruins in England; indeed they are works of art on so great a scale, that they may well bear a rivalry with the original: the buildings are spread over the ground without any attention to effect being produced by their exterior, unconnected with the scenery; the object seems to be to furnish pretexts for excursions within the enclosure, which is so disposed as to appear more extensive than it really is. Much labor has been expended upon the walks, which, in places, resemble mosaic work. These gardens were a favorite resort of Kien-long, whose dining-room and study were shown to us; in the latter was a black marble slab, with a poem inscribed upon it, composed by his majesty, in praise of the garden. The characters were particularly well executed. The trees in the garden were chiefly the olea fragrans and some planes."

(Vol. i. p. 493.)

476. The villa of Puanke-qua, belonging to one of the principal Hong merchants of Canton, is interesting as a specimen of Chinese taste in laying out grounds; the great object is to produce as much variety as possible within a small space." (Vol. ii. p. 186.)

477. The Fatee gardens at Canton, belonging to rich individuals, and the resort of the fashionable, "consist of straight walks lined with flower-pots, containing the curious and beautiful plants of the country." (Vol. ii. p. 186.)

478. A plan of a Chinese garden and dwelling, executed at forty-five leagues from the city of Pekin, was taken by Stornberg, a gardener, who was several years in that country, and is given by Kraft in his Plans, (Plans, &c., partie 2. pl. 95.) If this plan (fig. 37.) is really correct, it seems to countenance the idea of the modern style being taken from that of the Chinese. The house of the mandarin, its proprietor, contains an entrance under a triumphal arch (a), barracks or offices (b), fountains (c), entrance-gate for dignified persons (d), vases of odors (e), officers' dwellings (f), residences of those in waiting (g), fountains (h), residence of the proprietor (i), apartments for mandarin ladies (k), triumphal arch (l), bagnio and room for sports (m), a pa-
vilion on a rock (r), building for the practice of archery (o), green-house (p), pleasure-house (q), and a rock under which the river passes and forms a waterfall (r). (Kraft, p. 70.)

479. Horticulture in China is generally considered to be in an advanced state; but, we have no evidence that the Chinese are acquainted with its scientific principles, and especially with the physiology of plants. The climate and soil of so immense a tract as China, are necessarily various; and equally so, in consequence, the vegetable productions. Besides the fruits peculiar to the country, many of which are unknown to the rest of the world, it produces the greater part of those of Europe; but, excepting the oranges and pomegranates, they are much inferior. The orange was introduced to Europe from China, and the pine-apple to China from South America, by the Portuguese in the sixteenth century.

The Chinese are supposed to have a number of culinary vegetables peculiar to themselves. They are said to cultivate edible plants, even in the beds of their rivers and lakes, and among others, the pi-tsi or water chestnut (Scirpus; tuberosus, Rox.), which yields tubers of a farinaceous quality and agreeable taste. The convolvulus reptans (Lour.) grown in ditches, amaranthus polygamus, and tristis, Sinapis Pekinensis, and some others used as pot-herbs. They have also a particular variety of brassica, used both as a salad and in a boiled state. (Abel’s Journal.) Le Comte, Du Halde, Eckeburg, and others, praise the manner in which the Chinese cultivate culinary vegetables, which, they say, are abundant in their gardens, and form the chief part of the nourishment of the lower orders. They add, however, that the greater part of their fruits do not equal ours; either because the Chinese are ignorant of the art of improving them, or because they do not give themselves the trouble. Their grand object is to cultivate corn and rice; and they are ignorant of botany. One of the authors of these remarks, Captain Eckeberg, has published, in the transactions of the academy of sciences of Stockholm, a treatise on the rural economy of this people; and Count Lasteyrie has collected what is known on the same subject. The British works, published after different embassies, contain accounts of their modes of propagation, by inarching and local radication; of their dwarfing forest-trees, producing double-flowers, monstrous unions, and various other exertions, in the way of conquering nature. It is a singular fact, that with all this practical skill, the Chinese do not appear to be very busily occupied, otherwise than cultivating their rice. The Pekin Gazette, an official publication in which all notices relative to any variation or change in their practices are made public; and to the circumstance of “potatoes and cabbages having been cultivated in the neighbourhood of Macao for upwards of half a century, and although highly profitable and productive, yet the number of growing them has not reached Canton, perhaps has not even extended five miles.” It is impossible, this writer observes, to establish any distinction between the agriculture and horticulture of the Chinese merely from the plan of cultivation, the same ground being alternately cropped with grain and culinary esculents.

The cultivation of flowers and plants of ornament seems very general in China. The beautiful varieties of camellia, azalea, rosa, chrysanthemum, and of various other genera, are well known natives of that country.

480. Hot-houses are not unknown in China. Watthen (Journal of a voyage to China, &c. 1814.) describes the villa (fig. 38.) of Pon-qua-qua, a retired merchant and mandarin, as containing a green-house (a), an aviary (b), a banqueting room open on one side; a garden with the walks bordered with porcelain pots of orange-trees and camellias; and an immense Banyan-tree (Ficus Benghalensis).

Sect. III. Gardening in Anglo-North America, or the United States and British Provinces.

481. The use of gardens in North America is very general, though chiefly confined to horticultural or useful productions. B. McMahon, in his American Kalendar, says, “America has not yet made that rapid progress in gardening, ornamental planting, and fanciful rural designs, which might naturally be expected from an intelligent, happy, and independent people, possessed so universally of landed property, unoppressed by taxation or tithes, and blest with consequent comfort and affluence.” (Pref.)

McMahon is a seedman in Philadelphia, and “has connected with the seed-trade a botanical, agricultural, and horticultural book-store.” His work is the first of the kind which has appeared in America, and includes every department to be found in our calendars. Ample instructions are given for growing the pine, vine, melon, and other delicate fruits, and also for the forcing departments both of the flower and kitchen gardens; but we cannot get from the work any thing as to the extent of American practice in these particulars. From this, and the few other American books on gardening, we submit what we have been able to glean, as to the state of horticulture, botanical gardening, and timber-trees.
GARDENING AND AS

The middle states of America, he says, "possess a climate eminently favorable to the production of the finer liquor and table apples; and the limits of that district of country which produces apples of the due degree of excellence are for both purposes the Mohawk river in New York, and for both purposes the James river in Virginia. Apples grow well in other places, but that exquisite flavor for which the Newton pippin and Exopus Spitzenberg are so much admired, and which has given such high reputation to the cyder from the Hudson river, is not always produced even there, and can only be retained with the care here described. Cold and heat, are equally necessary to the production of a fine apple, and neither must predominate in too great a degree. Some European cyder fruits have recovered their reputation by being transplanted to the more genial climate of America, where the growth of trees compared with Europe is as five to three."

The peach is a native of South America; in North America, Coxe says, it is subject to a malady, which no remedy can cure, nor cultivation avert. This is a worm which destroys the roots and trunk of the tree. The only palliative is fresh soil. (Preface, p. 11.)

Plums and cherries are natives of the United States, and wood-cuts are given in Coxe's work of the principal sorts of these fruits commonly cultivated, and which are chiefly those well known in Britain.

The vine, Dr. Dean observes (New-England Georigcal Dictionary, in loco Massachusetts, 1797), "may, without doubt, be cultivated in every latitude of the North American states. They are wild in the neighborhood of Boston." He has known a good wine made from the juice of wild purple grapes; and seen excellent eating grapes produced in the American gardens, without any extraordinary culture.

The greater part of states, and particularly New England in the common way of planting, but is not so large nor so early as when raised on dung.

Culinary vegetables, Kingdom states (America, &c. 1820), grow in the same perfection as in England, except the cauliflower and some species of beans. Water-melons, musk-melons, squashes, sweet potatoes, cucumbers, &c. arrive at great perfection.

Those who wish to grow sugar must go south of 32°; cotton, south of 36°; and for corn the best latitude is from 36° to 41°. This is the work after a settlement is to plant a peach and apple orchard, planting the trees alternately. The peach, being short-lived, is soon removed, and its place covered by the branches of the apple-trees. (Kingdom, 5.)

The seeds of pumpkins are scattered in the field, when planting the corn, and no further trouble is necessary than throwing them into the waggons when ripe. They weigh from thirty to forty pounds each; and cattle and hogs are fond of them. In Maryland, Virginia, and the neighbouring provinces of the United States, peaches are propagated invariably from the stone. The fruit is used for feeding hogs, and distilled for brandy. In Virginia, the prickly pear abounds in the woods, and is reckoned a cooling, grateful fruit. (History of Hort. Trees, vol. ii.)

In Lower Canada, the fruit is neither remarkable for goodness nor cheapness, except strawberries and raspberries, which are very abundant. Apples and pears are sent from Montreal to Quebec, and sell for about the same price as in England. Oranges and lemons are imported from England, and are sometimes very excellent. Gooseberries, plums, and melons are plentiful; but currants, cherries, walnuts, and filberts are scarce. (Kingdom, 91.)

Upper Canada is very fertile. At Montreal are extensive orchards. Here the sugar-maple is abundant, and pierced for sugar when the sap begins to rise. A tree twenty inches in diameter will yield five pounds of sugar usually, and sometimes more for thirty years. Pot and pear-trees are made from the fellied trees. Beech yields at the rate of 219 lbs. for 1000 lbs. of ashos, and most other trees less. Sun-flowers are abundant, but oil is not extracted from them as in the United States. (Kingdom, 82.) A great variety of fruit-trees may be had at the nursery-gardens at Montreal. The apples from thence are considered superior to any other. The peach-trees are introduced into the orchards from York to Amherstburg. Cherries, walnuts, chestnuts, hickery, hazel, and filbert nuts grow wild; as do gooseberries, strawberries, blueberries, cranberries, and black currants.

483. Botanic gardening. — America is rich in botany, especially in trees. Dr. Hosack, in the preface to his Hortus Elginensis, observes, "that, although much has been done by the governments of Great Britain, France, Spain, Sweden, and Germany, in the investigation of the vegetable productions of America; although much has been accomplished by the labors of Catesby, Kalm, Wangenheim, Schoepf, Walter, and the Michaux; and by our countrymen, Clayton, the Bartrams, Calden, Muhlenburg, Marshall, Cutler, and the learned P. Barton of Pennsylvania, much yet remains to be done in this western part of the globe."

There were in America, at an early period, men who recommended the necessity of instituting botanic gardens, as Lieutenant-Governor Calden and Dr. Middleton of New York, in 1769; and, upon the revival of the medical school in Columbia college, in 1792, a professor of botany was appointed, and Dr. Mitchell was appointed professor. Dr. Hosack succeeded Dr. Mitchell, and the result was, first, the latter professor's establishing a botanical garden at his own expense, and afterwards government purchasing it of him for the benefit of the medical schools of New York, and it is now known as the New York Botanic Garden.

484. The botanic garden of New York contains twenty acres; the first catalogue was published in 1806, and the second, in 1811, containing nearly 4000 species. (Statement &c. as to the Elgin Botanical Garden, by Dr. Hosack, New York, 1811.)

485. The first American Flora appeared in 1816, by F. Pursh, a German botanist, who spent nearly twelve years beyond the Atlantic in botanic travel, and in the management of two botanic gardens, the last that of Elgin. From the preface to this work we are enabled to give the names of the principal botanic gardens in the United States. In British America there are none. The first gardens Pursh saw were the old established gardens of M. Marshall, author of a small treatise on the forest-trees of North America. These were rather on the decline. The botanic garden of J. and W. Bartram on the banks of the Delaware, near Philadelphia, was founded by their father under the patronage of Dr. Fothergill. W. Bartram is author of travels in North and South Carolina.
and of an introduction to botany. The garden of W. Hamilton, Esq. of Woodlands, is one of the best in America; that of Elgin has been already mentioned.

486. Forest-trees. — Michaux's work on the trees of America is the fruit of two voyages, in 1802 and 1806. The number of trees which in America grow above thirty feet high, which he has seen and describes, is one hundred and thirty-seven, of which eighty-five are employed in the arts. In France there are only thirty-seven which rise to that height, of which eighteen serve to form timber-plantations, and of these seven only are employed in civil and marine constructions. Michaux acknowledges his obligations to W. Hamilton, "an enlightened amateur of the sciences and arts," who pleases himself in uniting at his magnificent residence at Woodlands, near Philadelphia, not only all the useful vegetables of the United States, but those of every country of the world, which may offer any interest in the arts or in medicine. (Introduction, 16.) From the Transactions of the Society of Agriculture of New York, we learn, that hawthorn hedges and other live fences are generally adopted in the cultivated districts; but the time is not yet arrived for forming timber-plantations.

SECT. IV. Gardening in Spanish North America, or Mexico.

487. The gardening of the Mexicans is described by the Abbé Clavigero, in his History of Mexico. According to this author, when the Mexicans were brought into subjection to the Calhuan and Tepanec nations, and confined to the miserable little islands on the lake, they ceased for some years to cultivate the land, because they had none until necessity and industry together taught them to form moveable fields and gardens, which floated on the waters of the lake. The mode of forming these of wicker-work, water-plants, and mud, may be easily conceived. The boat or basis is commonly eight perches long by three broad. They first cultivated the maize and useful plants only, but afterwards "there were among them gardens of flowers and odoriferous plants, which were employed in the worship of the gods, and served for the recreation of the nobles." At present they cultivate flowers, and every sort of garden-herbs upon them, all of which thrive surprisingly. In the largest gardens there is commonly a little tree, and even a little hut to shelter the cultivator, and defend him from rain or the sun. When the owner of a garden wishes to change his situation, to remove from a disagreeable neighbour, or come nearer to his own family, he gets into his little vessel, and by his own strength alone, if the garden is small, or with aid, if it be large, he tows it after him, and conducts it where he pleases with the little tree and hut on it. That part of the lake where the gardens are, is a place of infinite recreation, where the senses receive the highest possible gratification. The Mexicans were extremely well skilled in the cultivation of kitchen and other gardens, in which they planted, with great regularity and taste, fruit-trees, and medicinal plants and flowers. The last of these were much in demand, bunches of flowers being presented to persons of rank, kings, lords, and ambassadors, and also used in temples and private oratories.

488. The royal gardens of Mexico and Tezcuco, and those of the Lords of Iztapalapan and Huantepec, have been much celebrated. One, belonging to the Lord of Iztapalapan was laid out in four squares, and planted with great variety of trees, through which a number of roads and paths led, some formed by fruit-bearing trees, and others by espaliers of flowering shrubs and aromatic plants. It was watered by canals, and had in the centre a fish-pond four hundred yards in diameter, where innumerable water-fowl resorted. Hernandez says, this garden contained many foreign trees. The garden of Huantepec was six miles in circumference, watered by a river, planted with numerous species of trees and plants beautifully disposed, along with pleasure-houses. Many foreign plants were cultivated, and every kind of medicinal plant belonging to that clime, for the use of the hospital which they founded there. Cortez, in a letter to Charles V. in 1522, told him that this garden was the most extensive, the most beautiful, and most delightful which had ever been beheld. Bernard Dias and other authors concur in the same opinion. The Mexicans paid great attention to the preservation of woods, which supplied them with timber and fuel. (History of Mexico, i. 379.)

489. A conventual garden at Mexico is described by Humboldt (Voyage, &c. liv. iii. chap. 8.), in 1803, as one of the finest he had ever seen. The convent was a very picturesque building, and in the garden were immense groves of orange-trees, peaches, apples, cherries, and other fruit-trees of Europe.

490. The royal botanic garden, in the promenade (cours) of the vice-king's palace, Humboldt describes as small, but extremely rich in vegetables, rare, or interesting for industry and commerce.

491. The floating gardens, or chinampas, mentioned by the Abbé Clavigero, he says still exist. They are of two sorts; the one mobile and blown here and there by the winds, and the others fixed and united to the shore. The former alone merit the appellation of floating, and they are diminishing day by day. He assigns to them the same origin as the Abbé Clavigero; but thinks it probable that nature also may have suggested the first idea,
and gives instances of small pieces of surface netted with roots and covered with plants being detached from the marshy shores of other American lakes, and floating about in the water. The bean, pea, apple, artichoke, cauliflowers, and a great variety of other culinary plants are cultivated on them. In the ninth chapter of Humboldt's work will be found an ample account of the useful plants of Mexico. It is singular, that the potatoe, which one would have imagined should have been introduced from the southern continent to Mexico, should have been first carried there from Old Spain. It is not, Humboldt says, a native of Peru, nor to be found between latitudes 12° and 50°. In Chili it has been cultivated for a long series of ages, where there is a wild sort with bitter roots.

Sect. V. Gardening in South America.

492. Gardening appears to be little known in South America, excepting in the European colonies. It is the country, however, of some of our most valuable culinary productions, as the potato; of the most exquisite fruits, as the pine-apple and Cheremoyas; and of many of our most beautiful flowers, as the dahlia. There is a species of Chili pine (Araucaria), which is considered the largest tree in the world: it has an erect stem, and the seeds are a farinaceous food, and as large as chestnuts. This tree, it is thought, may yet be acclimated, and clothe our northern mountains. The whole of South America is rich in vegetable productions, many of which are unknown in Europe; but there are now a number of collectors in that country, for the purposes of botany and horticulture.

Sect. VI. Gardening in the British Colonies, and in other Foreign Settlements of European Nations.

493. Gardening cannot be displayed to much advantage in distant and precarious territorial appendages, where the object is most frequently to acquire the means of returning to garden at home. In permanent settlements, however, such as the Cape of Good Hope, Van Diemen's Land, &c. gardening will be resorted to as an art of necessity.

494. The gardening of any colony will always resemble that of the parent country. It is evident, that wherever a people establish themselves, they will also establish, in part, their arts or manners. All colonists carry with them the seeds of the useful vegetables, which they have been accustomed to cultivate; and subsequently they attempt to introduce the more delicate or luxurious fruits and flowers.

495. The European governments have established colonial botanic gardens wherever their utility has been made apparent; and in this, as well as in the ornamental part of gardening, it is but fair to state, that the French and Dutch have been before England in point of time, as well as in point of excellence. The Dutch had a fine government garden at the Cape of Good Hope, and another at Batavia in the middle of the seventeenth century. The French had a garden in Cayenne, in 1630. The first colonial botanic garden established by the English, was that of Jamaica, about 1780. It must also be confessed, that our botanic gardens have hitherto been less useful to horticulture than the government or residence-gardens, and the botanical gardens of the Dutch; because in these last, useful plants are the principal objects; whereas in ours, number of species is, or seems to be, most attended to. Horticulture, in civilised countries, may be deemed sufficiently protected and encouraged by its own immediate contributions to the wants and desires of mankind; but in barbarous countries every art requires protection at the first establishment of a colony. Perhaps there is no way in which man in a civilised state can promote the progress of rude society more, than by introducing new and useful fruits and herbs. The numerous vegetables now used in the domestic economy of civilised society have been collected from various and opposite parts of the globe. Where would be the enjoyments of a European table, if they depended on our native herbs and fruits? Europe in this respect is under great obligations to Persia and Egypt; and these countries, and many others of Asia, Africa, and America, are now in their turn receiving great benefits from the colonies of Europeans who settle on them.

496. As examples of the use of gardening in colonisation, we may refer to the Cape of Good Hope, which possesses at present all the best culinary productions and fruits of Europe and Asia. Till 1660, that the Dutch established a colony there, it had no other fruits than the chestnut, a nut like the wild almond, and what is called the wild plum; and no culinary plants but a sort of vetch. The first shipment of convicts was landed at Sidney Cove in 1789, and since that period, every horticultural product of Britain has been introduced there, and cultivated with one or two exceptions, in the greatest perfection.

497. The influence of gardening comforts, together with instruction, on uncivilised countries, both as to society and climate, and finally on the whole globe itself, cannot be foreseen. The now trackless deserts of arid sand in Africa, may be destined at some future age to be watered and cultivated by the superfluous population of the other quarters of the world. The evaporation and coolness produced by a surface cultivated chiefly by irriri-
HISTORY OF GARDENING. Part I.

39

In every agitation, the whole temperature. J. mangostan, climate, tropical year have been in desert. Also an awning, Town-houses of here.

The native products of these islands are various and excellent, and have been greatly increased by fruits and spices, introduced from the East Indies and other places. Among these it may be sufficient to mention the pineapple, bread-fruit, mangostan, durian and cinnamon. There is a large botanic garden at St. Vincents, and others at Trinidad and Martinique, supported by their respective governments. There was formerly one of seventy acres in Jamaica, of which some particulars deserve here to be recorded. "The botanic garden of Jamaica was originally begun by J. Hinton, Esq., and afterwards bought by government, and enlarged as to contain seventy acres. One of the objects of its establishment was to preserve, without artificial means, the production of various climates. Such a project could only be executed in a tropical latitude, where the various elevations of the ground would regulate the required temperature. The site chosen for this purpose is about seven miles from Kingston, on the side of the Liguanea mountain, the summit of which is 3600 feet above the level of the sea. Here, ascending from the base, are found the productions of the various countries of the earth; every change of situation represents a change of latitude, and the whole surface of the mountain may be clothed with the appropriate vegetation of every climate, from the pole to the equator. By means of this noble and useful establishment, the vegetable productions of various climes have been naturalised to the soil, and the plantations of Jamaica have been enriched with many valuable trees, shrubs, and plants, which were heretofore unknown in the island; of these may be mentioned cinnamon, mangostan, mangoes, sago, bread-fruit, star-apple, camphor, gum-arabic, asafetida, &c. introduced from a French ship captured in 1782." (Edwards's Jamaica, 1881.) In the year 1812, the whole was sold by the House of Assembly, for the small sum of 4000£. to an apothecary in Kingston. It is impossible to avoid regretting such a circumstance. Some account of the garden of St. Vincents will be found in the Transactions of the Society of Arts. Pine-apple plants, and also ripe fruits, are frequently sent from the West Indies to Europe, and arrive commonly in a fit state for planting and the dessert.

500. East Indies. Bengal, the province longest under British subjection, resembles Egypt, in consisting of one immense plain of fertile soil, watered by the Ganges, which overflows it annually. Calcutta, the capital, has been subject to the English since 1765, but it does not appear that much has been yet done by the East India Company, in the way of gardening.

* In the park at Barrackpore, about sixteen miles from the capital, are the unfinished arches of a house begun by the Marquis of Wellesley, but discontinued by the frugality of the Court of Directors. There is also a magnificent garden, not far distant, which contains a botanic garden, and has been formed by the British in most of the East Indian settlements. We may cite, as an example, Dr. M'Kinnon's cottage (fig. 39.), in the neighbourhood of Madras. It is thatched with palm-leaves. Town-houses and large country-houses are generally flat-roofed; and the roof shaded by an awning, serves as a banqueting-place. The botanic garden of Calcutta was founded in 1790, it is beautifully situated on the west bank of the river, and gives to one of its bendings, the name of Garden-reach. Above the garden there is an extensive plantation of teak, a tree not native of this part of India, but which thrives well here. This garden was under the direction of Dr. Roxburgh, well known as the author of a work on the plants of Coromandel. Maria Graham (Letters from India) describes it as rich in palms, mimosa, and parasitic plants, and as neatly kept. Seeds from this garden are sent annually to Kew and other European gardens; as well as to various British settlements in the East, as Ceylon, &c.

The orchard of Bengal is what chiefly contributes to attach the peasant to his native soil. He feels a superstitious veneration for the trees planted by his ancestors, and derives comfort and profit from their fruit. Orchards of mango-trees diversify every part of this immense country; the palmira abounds in Bengal in the plains, and the various sorts which are not remote from the tropic. The date-tree grows everywhere, but especially in Bahar. Plantations of the areca, or Betel-palm, are common in the central parts of the country.

The cultivated vegetables of Europe have all been introduced into India. Potatoes grown there are deemed equal, if not superior, in quality to those of England. Asparagus, cauliflower, pease, and other esculent plants, are raised, but they are comparatively tasteless.

The desert of Europeans in Calcutta, is distinguished by a vast profusion of most beautiful fruits, procured at a very moderate expense, such as pine-apples, plantains, mangoes, pomeloes or shadoocks, melons of all sorts, oranges, custard-apples, guavas, peaches, and an endless variety of other orchard-fruits. Forest-trees do not naturally abound in Bengal; the tea-tree (Fretia grandis) is the oak of the East, and grows in abundance in the hilly kingdoms of Birman and Begum, whence Calcutta is supplied for the purposes of naval architecture. Whether it shall be found worth while to cultivate this tree in Bengal, appears very doubtful. The bamboo is the timber used in the general economy of the country. Hedges of native armed plants are occasionally used round gardens, orchards, and small enclosures.
501. Ceylon. All the productions of Hindostan are said to thrive here. General Macdowal, with the assistance of Dr. Roxburgh of Calcutta, made a valuable collection of exotics, which he left at Calombo in 1804. He introduced peaches, grafted and trained on espaliers, which bore at three years old. Gardeners, in hot climates, Cordiner observes (Account of Ceylon, vol. ii. p. 387.), are much perplexed by the trees which are deciduous in Europe, retaining their leaves all the year. Apples and asparagus succeeded well in this climate. The country is rich in botany, and abounds in palm-trees and plantains. Cordiner describes the cinnamon-groves as delightful. "Nothing can exceed the luxury of riding through them in the cool hours of the morning, when the air is cool and the sweetness of the spring blended with the glow of summer. Every plant in the garden is at all times clothed with fresh and lively green, and when the cinnamon laurels put forth their flame-colored leaves and delicate blossoms the scenery is exquisitely beautiful. The fragrance, however, is not so powerful as strangers are apt to imagine. The cinnamon-bark affords no scent when the trees are growing in tranquillity, and it is only in a few places that the air is perfumed with the delicious odor of other shrubs, the greater proportion of the flowers and blossoms of India being entirely destitute of that quality. Gentle undulations in the ground, and clumps of majestic trees, add to the picturesque appearance of the scene; and a person cannot move twenty yards into a grove without meeting a hundred species of beautiful plants and flowers springing up spontaneously. Several roads for carriages make winding circuits in the woods, and numerous intersecting foot-paths penetrate the deepest thickets. In sauntering amidst these groves, a botanist or a simple lover of nature may experience the most sublime delight which the vegetable creation is capable of affording, and the zoologist will not be less gratified by the variety, the number, and the strangeness of many of the animal kingdom." The Cingalese, as we have noticed (§), lay claim to the situation of paradise, and one of the animals peculiar to the country, the *Loris Ceylonicus*, Fischeri (fig. 40.), has been considered by some philosophers as aboriginal man. (Cordiner's Ceylon, vol. ii. p. 421.) The agriculture and gardening of the native Cingalese may be considered as one art, the objects of culture being edible roots, as the yam and grains, and spices, as the rice and pepper. Ample details are given by Dr. Davy in his Account, &c. of Ceylon.

502. Cape of Good Hope. A very fine garden was formed here by the Dutch about the middle of the seventeenth century, which is described in Lachman's Travels of the Jesuits (vol. i. let. 37.), and thus noticed by Sir William Temple. "It contained nineteen acres, was of an oblong figure, very large extent, and divided into four quarters, by long and cross walks, ranged with all sorts of orange-trees, lemons, limes, and citrons; each of these four quarters is planted with the trees, fruits, flowers, and plants, that are native and proper to each of the four parts of the world; so as in this one inclosure are to be found the several gardens of Europe, Asia, Africa, and America. There could not be, in my mind, a greater thought of a gardener, nor a nobler idea of a garden, nor better suited or chosen for the climate." Father de Premare says, "it is one of the most beautiful spectacles in the world;" and indeed it is not easy for a mere European traveller to conceive the magnificence of palm-trees and plantains in their native climates. Whether this garden still exists, we have not been able to learn, but as it doubtless contributed to introduce the horticultural productions of Europe to this part of the globe, it deserves to be remembered with gratitude to its founders.

The only indigenous fruits of the Cape, as already observed (496.), are the chestnut, and two stone fruits. Those that have been introduced into the colony are the grape, apple, cherry, plum, peach, nectarine, apricot, fig, orange, lemon, citron, pomegranate, almond, mulberry, guava, melon, and in short all the fruits esteemed by Europeans. No grapes of Europe are considered preferable to those of this colony. The colony of Capetown consists chiefly of vine-growers. They are of French extraction, possess farms of about 150 English acres, and the culture of the grape, with an elegant garden, generally occupies the whole. The lands are surrounded and divided by oak and quince hedges; and the vines, cultivated as in France and Germany, have the appearance of plantations of raspberries. The Cape-market is richly supplied from these gardens. Between Table Bay and False Bay, are the two farms producing the Constantia wine. Here most of the above fruits thrive; but gooseberries, currents, plums, and cherries do not succeed at all. The ornamental plants of the Cape are well known; to them we are indebted for almost all our heaths, ixias, Diosmae, pelargoniums, and many other genera. (Kingdom's British Colonies, p. 81.)

503. New South Wales. There are two colonies established in this extensive territory and its adjoining islands; the one at Sidney, in 1788, and the other at Van Diemen's Land some years afterwards. The botanical riches of New South Wales, and the singular aspect of the native plants, are well known. There are gardeners and botanists esta-
blished in and near Sidney, who collect seeds for England, and other parts of Europe; and it is in contemplation to establish a government botanic garden there, which will doubtless be of essential service in collecting and preserving native plants. The climate and soil of both settlements are favorable for horticulture. Potatoes, cabbages, carrots, parsnips, turnips, and every species of vegetable known in England, are produced in this colony. The cauliflower and broccoli, and the pea, arrive to greater perfection than in Europe; but the bean and potato degenerate. The climate is too hot for the bean, and the potato is only grown to advantage on new lands.

New South Wales is famed for the goodness and variety of its fruits; peaches, apricots, nectarines, oranges, grapes, pears, plums, figs, pomegranates, raspberries, strawberries, and melons of all sorts, attain the highest degree of maturity in the open air; and even the pine-apple may be produced merely by the aid of the common glass frame. The climate of Port Jackson, however, is not altogether congenial to the growth of the apple, currant, and gooseberry, although the whole of these fruits are produced there, and the apple in particular in very great abundance; but it is decidedly inferior to the apple of Britain. In Van Diemen's Land these fruits arrive at the greatest perfection; and as the climate of the country to the westward of the Blue Mountains is equally cold, they will, without doubt, attain there an equal degree of excellence. Of all the fruits which are thus enumerated, as being produced in the colony, the peach is the most abundant and the most useful. The different varieties which have been already introduced succeed one another in uninterrupted succession from the middle of November to the latter end of March, thus filling up an interval of more than four months, and affording a wholesome and nutritious article of food during one-third of the year. The tree thrives in all soils and situations, and its growth is so rapid, that if you plant a stone, it will, in three years afterwards, bear an abundant crop. The fruit is the food of hogs, and when thrown into heaps, and allowed to undergo a proper degree of fermentation, is found to fatten them very rapidly. Cyder is also made from it; and the lees also fatten hogs. (Kingdom's British Colonies, p. 594.)

504. Van Diemen's Land. This settlement does not contain either such a variety or abundance of fruit as the parent colony. The greater coldness of the climate sufficiently accounts for the former deficiency, and the recency of its establishment for the latter. The orange, citron, guava, loquat, pomegranate, and other fruits, which attain the greatest perfection at Port Jackson, cannot be produced here without having recourse to artificial means; while others, as the peach, nectarine, grape, &c. only arrive at a very inferior degree of maturity. On the other hand, the apple, currant, and gooseberry, and indeed all those fruits for which the climate of New South Wales is too warm, are raised here without difficulty. (Kingdom's British Colonies, p. 300.)

505. Cayenne. The French have a botanic garden, and several fine private gardens in the fertile colony of Cayenne. A very interesting account of this colony and its productions, natural and artificial, will be found in the Maison Rustique de Cayenne, published by Prefontaine in 1763.

506. Malta. There is a small botanic garden on this island, supported by the government; and a late governor, Sir A. Balls, is said (Letters from Malta, 1817) to have established public gardens at every village for the employment of the poor, and the dissemination of useful seeds and plants among the farmers. No success attended this measure, from mismanagement, as it is said, in the curators. Great part of Malta was originally little better than a bare limestone-rock; but this rock is full of cracks or vertical fissures, which are filled with calcareous soil washed down from the surface. This is dug up by the inhabitants, and re-spread over the surface; and by means of irrigation and careful culture, the cotton-plant is grown as an article of general economy. In the more fertile part of the island, the orange-tribe are grown, and the Maltese, or red-fleshed orange, being a variety in much esteem, there is some demand for young trees as articles of foreign commerce. These trees are more scientifically trained and inoculated than those of Genoa.

---

BOOK II.

GARDENING CONSIDERED AS TO ITS PROGRESS AND PRESENT STATE UNDER DIFFERENT POLITICAL AND GEOGRAPHICAL CIRCUMSTANCES.

507. Every art must be affected by the government under which it is exercised, either directly by its laws and institutions, or indirectly by the state of society as modified by their influence. Gardening and agriculture differ from other arts in being still more affected by climates than by governments; the influence of the latter is temporary or accidental, while that of the former is absolute and unchangeable.

---

CHAP. I.

Gardening as affected by different Forms of Government, Religions, and States of Society.

508. All governments may be reduced to two classes; the primitive, or those where the people are governed by the will or laws of one or a few persons independently of the
people; and the rational, or those where they are governed by laws formed by a congre-
gated assemblage of their own body. The former are calculated for rude and ignorant
ages, when man, in a state of infancy, is governed by a king, as children are ruled by
their parents; the latter, for more enlightened times, when a people, like children
arrived at manhood, are capable of thinking for themselves and acting in concert.

509. Society is either fixed or free. In a fixed state, property is hereditary, and one
part of the people are perfectly independent, and the other dependent; in a free state,
men may belong to either class, according to their talents and the chances of life. In
the former case, a man's condition in society depends on chance; in the latter on chance
and skill combined.

Sect. I. Gardening as affected by different Forms of Government and Religion.

510. Gardening as an art furnishing a part of the necessaries of life, may be practised
under any form of government; and wherever there is some liberty and security of
property, its productions of necessity and comfort will ensure its use. Wherever
civilised man has a house, he will always have an accompanying spot for roots and
legumes; and wherever he enjoys a farm, he will desire orchards or vineyards for
fruits or wine, and copse-woods and forest-trees for fuel and timber: shelter, shade,
and ornament will follow in due time. Under paternal forms of government, the taste
of the monarch will generally be indiscriminately followed by such of his subjects as
can indulge in it; and thus fashion will assume the province of reason. Such a
government must be favorable or unfavorable to the arts, according to the taste of its
chief. Monarchs generally love splendor more than elegance or use; and in gardening
are less likely to render its useful productions common among their subjects, than to
increase the luxurious enjoyments of a few wealthy courtiers. This was exemplified in
Louis XIV., who set the fashion not only in France but in Europe; but never, in all
probability, added a foot of ground to the garden of a single cottager, or placed an
additional cabbage or potatoe on his table. Under republican governments, the first
tendency of public feeling is to economy, and consequently to discourage those arts, or
branches of arts, which minister to luxury. Gardening, under such circumstances,
will be practised as a useful art, rather than one of design and taste; and more for its
substantial benefits and scientific objects, than for its extraordinary productions and
peculiar gratifications. In the beginning of the French revolution, we find the com-
pilers of the Encyclopaedia (see the vol. sur l’Aratoire et Jardinage) holding light the
productions of forcing-houses, and the taste for double flowers. In America, the same
simplicity of taste prevails, and also in Switzerland.

511. Gardening in all its branches will be most advantageously displayed where the
people are free. The final tendency of every free government or society is to conglome-
rate property in irregular masses, as nature has distributed all her properties; and this
irregularity is the most favorable for gardening both as a necessary, convenient, and
elegant art. A republican or representative government and a commercial people may
be reckoned a case highly favorable to the arts, of which Holland, Genoa, and Venice,
formerly, and this country, at present, may be adduced as examples. Under mixed
governments, where there is a representative body, and a first or executive magistrate, his
taste will naturally have considerable influence on that of the people, as in Charles the
Second's time in England; unless, as sometimes happens, the king or executive officer's
taste is behind that of the people, in which case if the people be free and enlightened, the
arts of design and taste will, as they ought, become a republic, governed by its own
laws. This last state has in some degree taken place in England since the accession of
the Brunswick line, a fine illustration of which is given by Eustace (Tour, i. 608.), in
comparing the taste exhibited in the royal palaces built or altered by this race, with that
displayed in the residences of private English gentlemen since the revolution.

512. The religion of a people is calculated to have some effect on their gardening. Those
religions whose offices are accompanied by splendor and show, and which have numerous
fetes and spectacles, will be favorable to the culture of flowers and plants of ornament;
and those which forbid, at certain seasons, the use of animal food, will in some degree
encourage the production of fruits and culinary vegetables. Where those alternating
days of rest, of such antiquity in society and so conducive to the comfort of the
laboring classes, (Graham's Sabbath, Pref.) are to be spent wholly or partly in recreative
enjoyments, encouragement will be given to public gardens of different kinds; but
where they are to be spent in a devotion founded in fear, and consequently gloomy and
austere in its offices, such a religion cannot be said to encourage gardening. The
religions of Italy and Scotland afford examples of each of these cases.

Sect. II. Gardening as affected by different States of Society.

513. In mixed states of society, where property is in few hands, and the population
consists chiefly of lords of the soil and of slaves, the immensely rich may accomplish
great designs, which shall astonish by their magnificence; but taste among such a people is not likely to be refined; works of art are only prized as marks of wealth; their merit is not understood, and therefore, declining in interest after the first burst of surprise, they are soon viewed with indifference, and afterwards neglected or destroyed. Gardening, in such circumstances, is not likely to be improved in any of its branches, nor the use of gardens rendered general among any part of the population. Russia and Poland may be referred to as examples.

514. In free states of society, where commerce is a leading pursuit, and property is irregularly distributed among all classes; where there are wealthy, rich, and thriving citizens, and where the comforts of life are known and relished by every class, gardening is likely to prosper in all its branches. The first-rate gardens of the wealthy will be an example to the rich, act as a premium to operative gardeners and artists, and encourage commercial gardens. The fine gardens displayed by the wealthy commercialist will act as a stimulus to the independent gentleman, too apt to be stationary in his improvements. The retiring tradesman will aspire to the same excellence as the merchant, and stimulate him in his turn. Cottage-gardens will be found real ornaments to the country, and supply useful food and agreeable fruits to the laboring class of society, who, as they become more enlightened, will prefer employing their leisure hours in this way, rather than in grosser pleasures or habits. This was formerly the state of Holland, and is, in some degree, at present, that of Britain.

515. In free states of society, where agriculture is chiefly followed, where property continues much divided, and mankind, as will always be the case under such circumstances, are sober and rational, the useful branches of gardening will be generally practised and much improved. Wholesome culinary vegetables will be enjoyed by all classes, and agreeable fruits by most of the inhabitants. Switzerland may be referred to as an example.

516. Times of peace and commercial prosperity, under any government or state of society, will be more favorable than their opposites. The long and flourishing peace of the two first empires, Sir W. Temple observes, gave earlier rise and growth to learning and civilisation, and all the consequences of them, in magnificence and elegance of building and gardening; whereas Greece and Rome were almost perpetually engaged in quarrels and wars, either abroad or at home, and so were busy in actions done under the sun, rather than those under the shade.

517. In mixed states of society, where a part of the population are privileged orders or hereditary proprietors, and the rest partly free and partly dependent, gardening is likely to be encouraged, more especially as an art of design. The proprietor of an entailed territory may be said to enjoy a sort of tangible immortality; for by establishing in his person and estate a sort of local and corporeal connection between his ancestry and posterity, he sees neither beginning nor ending to his life and property. Such a being is anxious to distinguish his little reign by some permanent improvement; and those which are most likely to answer his purpose will be building or gardening. However distant the expected benefits of his efforts, they are sure to be enjoyed; and even if he exceeds his income, and contracts debts which he cannot pay, he knows that the labor and property of others, which he has embodied on his estate, will remain for its benefit, and that posterity will give him credit for zeal and ambition. But partial rights of this sort are much more injurious than beneficial to society, by giving the privileged party a legal title to contract debts which he is not able to pay. They are remains of those feudal or primitive institutions which, as mankind become enlightened, will be swept away, with various other antiquated customs and absurdities, till man at last, whatever may be the circumstances of fortune or family under which he may be ushered into society, will be left to sink or rise in wealth and respect, according to his personal merits. Though the nobility of Britain have fewer exclusive privileges than those on the continent, yet there are not wanting instances of these privileges being abused; and as an example of a man creating sumptuous gardens and forming fine collections of plants, without being able to pay for them, or liable to be put to personal inconvenience on that account, we may refer to George, the third duke of Marlborough.

Chap. II.

Gardening as affected by different Climates, Habits of Life, and Manners.

518. All gardening is relative to climate and purpose. It is obvious that gardening, in so far as respects the culture of plants, must differ in different climates, some of which will be found favorable for fruits, others for flowers, for culinary vegetables, and for timber-trees. Considered as an art of design, and as furnishing agreeable views, and
scenes for exercise or recreation, it will be found to vary, not only with the climate, but with the surface of the country, and the habits and manners of society.

519. The gardening of every country must vary according to the climate; and the practice of the art in one country cannot be applied to any other, unless that other greatly resemble the former in climate. "Useful hints," Nell observes, "may no doubt be occasionally drawn from observing the modes in other countries. But it is scarcely necessary to remark, that in warm climates the practice must differ very widely from that which obtains in the temperate or the cold. In the former, the plants which require to be fostered in our stoves, either grow spontaneously, or are cultivated in the open fields, while the greater part of our common pot-herbs refuse to flourish in sultry regions. Again, the far northern countries of Europe, Sweden, Norway, and Russia, possess peculiarities of climate: snow covers the soil throughout the winter, and the summers are uninterruptedly bright and warm. Even in Britain, such is the difference of climate between the favored countries of the south-west of England, and that part of the island which lies to the north of the Cheviot Hills, that the same rules cannot be applied to both, without very considerable modification. The horticulture of the north of France, of Belgium, Holland, and Denmamk, may, in general, be considered as approaching to that of South Britain; and these countries may frequently afford mutual lessons to each other, each availing itself of the other's discoveries, and adopting its improvements."

520. The finest climate for fruits, according to Sir William Temple, is that of Assyria, Media, and Persia. "Those noble fruits, the citron, the orange, and the lemon, are the native product of those noble regions, and though they have been from thence transplanted and propagated in many parts of Europe, yet they have not arrived at such perfection in beauty, taste, or virtue, as in their native soil and climate." "The reason of it can be no other than that of an excellent and proper soil being there extended under the best climate for the production of all sorts of the best fruits; which seems to be from about twenty-five to about thirty-five degrees of latitude. Now the regions under this climate in the present Persian empire (which comprehends most of the other two, called ancienly Assyria and Media,) are composed of many provinces, full of great and fertile plains, bounded by high mountains, especially to the north; watered naturally with many rivers, and those, by art and labor, divided into many more and smaller streams, which all conspire to form a country, in all circumstances, the most proper and agreeable for the production of the best and noblest fruits. Whereas, if we survey the regions of the western world, lying in the same latitude, between twenty-five and thirty-five degrees, we shall find them extend either over the Mediterranean sea, the ocean, or the sandy barren countries of Africa; and that no part of the continent of Europe lies so southward as thirty-five degrees; which may serve to discover the true reason why the fruits of the east have been always observed, and agreed to transcend those of the west. "Persia," Chardin observes, "is the first country of the world for beautiful and superb flowers, properly so called." The same observation will apply to the whole of India; but it is to be observed, that the flowers of these and other hot and dry countries are less odoriferous than in such as are temperate, and have a comparatively moist atmosphere. Moisture is favorable for conveying all odors, or, at least, for strengthening their impression on the olfactory nerves.

521. The most suitable climate for culinary or herbaceous vegetables is one temperate and moist; and in this respect Holland, England, and the more temperate parts of France and Flanders are before the rest of Europe. Sir William Temple, who lived much in Holland and the adjoining countries, says gardening, in his time, was there in the greatest perfection. The second country in Europe for culinary gardening and flowers, appears to us to be Lombardy; and considering that it is highly favorable for fruits, it may, as already observed, be considered the most propitious country in Europe for horticulture and ornamental gardening. There appear to be also corresponding situations in America, China, and New Holland, especially in the latter country which may one day become a second America. Wherever the fruit of the gooseberry and strawberry, and the bulb of the turnip and the head of the cabbage attain a good size, there the climate may be considered highly favorable to the growth of kitchen-crops, most kernel-fruits of Europe, and florists' flowers; but a warmer and drier climate is required for the richer stone-fruits, and most of those of the torrid zone.

522. The most suitable climate for timber-trees, when durability is an object, is a dry and rather elevated region. The resinous tribe produces the best timber in cold mountainous regions in every part of the globe. The oak, the chestnut, and the mahogany, delight in strong soils and moderate temperatures, such as skirt the bottoms of mountains. In general, no species of timber is found to be durable which has been produced in low, moist, warm situations.
523. Climates highly favorable for the productions of gardening, are often unfavorable to the progress of the art. In Persia and some parts of America, where the finest peaches are produced, the art of grafting is unknown or not practised; and, in general, in the hot countries, where melons, gourds, and other rapid-growing annuals so readily produce their fruit, the culture of culinary leaves and legumes is neglected. In the West India islands and great part of America, the gourd serves the purposes of the cabbage, turnip, lettuce, and spinach, and with garlic, onions, and yams, constitutes their principal culinary crops. Chardin, after enumerating the natural products of Persia, says, "we are not to conclude from thence that they have the finest gardens in the world; on the contrary, by a very general rule, there, where nature has been most abundant and liberal in her productions, art is proportionately rude and unknown; for, nature having gardened so well, almost nothing is left for art."

524. Climates and soils comparatively unfavorable for fruits and plants, are naturally conducive to skill in gardening. A very variable and unsettled climate, Neill observes (Gen. Report of Scotland, ch. ix.), tends to call into action all the powers of the mind, and to produce habits of increasing attention; and where a gardener is able to raise tolerable crops, both of the more tender fruits and vegetables, in climates and situations adverse to the production of either, he has doubtless more real merit in accomplishing his object, even though the articles should be somewhat inferior in quality, than he who, in a propitious soil and climate, raises them to the utmost perfection. Yet the merits of such a gardener are often overlooked, and the master, through ignorance or indifference, or a niggardly penuriousness of approbation, receives that as an effort of mechanical routine, which is due to a rare union of science, skill, and indefatigable attention.

525. The climate and country of England, Sir W. Temple considers as highly favorable for gardening. "Perhaps few countries," he says, "are before us in the number of our plants, and I believe none equals us in a variety of fruits, which may be justly called good, and from the earliest cherry and strawberry to the last apples and pears, may furnish every day of the circling year. For the taste and perfection of what we esteem the best, I may truly say that the French, who have eaten my peaches and grapes at Siene, in no very ill year, have generally concluded, that the last are as good as any they have eaten in France on this side Fontainbleau: and the first as good as any they have ate in Gascony; I mean those which come from the stone, and are properly called peaches, not those which are hard, and are termed pavies; for these cannot grow in too warm a climate, nor ever be good in a cold, and are better at Madrid than in Gascony itself. Italians have agreed, my white figs to be as good as any of that sort in Italy, which is the earlier kind of white fig there; for in the latter kind and the blue, we cannot come near the warm climates, no more than in the Frontignan or Muscat grape. My orange-trees are as large as any I saw when I was young in France, except those of Fontainbleau, or what I have since seen in the Low Countries, except some very old ones of the Prince of Orange's; as laden with flowers as can well be, as full of fruit as I suffer or desire them, and as well tasted as are commonly brought over, except the best sorts of Seville and Portugal. And thus much I could not but say in defence of our climate, which is so much and so generally decried abroad.—The truth is, our climate wants no heat to produce excellent fruits; and the default of it is only the short season of our heats and summers, by which many of the latter are left behind, and imperfect with us. But all such as are ripe before the end of August are, for aught I know, as good with us as any where else. This makes me esteem the true regions of gardens in England to be the compass of ten miles about London; where the incidental warmth of air, from the fires and steams of so vast a town, makes fruits, as well as corn, a great deal forwarder than in Hampshire or Wiltshire, though more southward by a full degree."

Sect. II. Influence of Climate and Manners on Gardening, as an Art of Design and Taste.

526. Taste in gardening depends jointly on the state of society, and on climate. Since the introduction of the modern or natural style of gardening into Britain, it has been a common practice to condemn indiscriminately every other taste as unnatural and absurd. If by unnatural, an allusion is made to the verdant scenery of uncultivated nature, we allow that this is the case; but we would ask, if for that reason, it follows that ancient gardens were not as natural and reasonable in their day, as any of the manners and customs of those times? Gardening, as a liberal art, is destined to create scenes, in which both beauty and use are combined; admitting, therefore, that both styles are alike convenient, to say that the modern only is beautiful, is to say that there is only one sort of beauty adapted to gardening; or that there is no beauty but that of the picturesque; or that all former ages, and every country, excepting Britain, is in a state of barbarism with respect to this art. If we take the term natural in a more extensive sense, and apply it to the climate, situation, condition, and manners of a people; and if we allow these to be natural, why may not their gardening be natural, as well as their particular customs and dress? The gardening we now condemn so unreservedly,
has subsisted, as we have seen, from the earliest ages in warm climates; and still prevails there, as well as in more temperate countries, whose inhabitants are not altogether ignorant of the modern style. It may, therefore, be said to have grown up with mankind, and at all events must be perfectly suited to the wants and wishes of the inhabitants of such countries.

527. The fitness and beauty of any style must depend on the purposes to which it is applied, and the kind of rural beauty already prevalent in the country of its adoption.

The gardens of the east, we have every reason to believe, were used more as arbors or conservatories in this country, than as places of exercise and active enjoyment. The object was repose, indolent recreation, sedentary or luxurious enjoyment, to breathe the fresh air, shaded from a tropical sun; to inhale the odor of flowers; to listen to the murmur of breezes or fountains; to the singing of birds; or to observe the minute beauties of the surrounding foliage, were, and still continue to be, the ordinary class of beauties desired in an eastern garden. A higher and much voluptuous kind, consisted in using it as a banqueting-place, bath, or seraglio, as is still the case in Turkey and Persia; in feasting the eyes with the sight of dancing beauties; in ravishing the ears with concerts of vocal or instrumental music, and in firing every sense with wine. Exercise was incompatible with that languor of body, which is attendant on a warm climate and a distant prospect; and want of security from wild beasts, and that privacy which selfishness or jealousy might dictate. "The Persians," Chardin observes, "do not walk in gardens so much as we do, but content themselves with a bare prospect, and breathing the fresh air. For this reason, they set themselves down in some part of the garden at their first coming in, and never move from their seats till they are going out of it." (Travels, ch. vi.) "Nothing surprises the people of the East Indies so much as to see Europeans take pleasure in exercise. They are astonished to see people walk who might sit still." (Kinderley's Letters from the East Indies, p. 182.) This to add to this, that the natural surface of warm countries is generally so parched and barren an aspect, that one would scarcely think it capable of producing anything but the very few plants which still have vigour enough to resist the extreme heats. (Rusell, Observations on these parts.) But what is common to every exertion of man, a desire of obtaining applause for the employment of wealth and skill, we shall include every object sought in an eastern garden. An eastern garden, therefore, appears to have been a collection of all those beauties found scattered about in general nature, in order to adapt them to the use and enjoyment of man.

528. The plan of an eastern garden was well calculated to attain the ends in view. Moderate extent and immediate connection with the house, are necessary and obvious ingredients in their design. The square form was adopted for the enclosure as the simplest; the trees ranged in rows, to afford continuity of shade; and the walks laid out parallel between them, to admit uninterrupted progress; that walk parallel to, and close under the house, as a raised platform or terrace, to give elevation and dignity to the house, to give the master a commanding view of the garden, and to serve as a connecting link between art and comparative nature. By leaving open plots or squares of turf in the areas, formed by intersecting rows of trees, a free circulation of air would be facilitated; and the same object, as Pliny informs us, is promoted by the quinconx, which admits the breeze from every quarter of the compass more readily than any other disposition. A picturesque or natural arrangement would have stagnated the air, and defeated one of the grand purposes in view. The same reasons would guide them in their choice of spreading broad-leaved trees; and to thicken their boughs, or deprive them of such branches were too low, or tended to destroy the balance of the tree, the pruning-knife would be occasionally applied. Water in every form suggests the idea of cooling; but agitated in cascades, fountains, or jets-d'eau, it is used to the best advantage, and the mist of the atmosphere is moderated in proportion to the evaporation which takes place. In still ponds or basins it has another property, that of reflecting the objects about it. Buildings, as arbors, aviaries, covered seats, banqueting-houses, baths, and grottoes, would become requisites for their respective uses, and would abound in proportion to the wealth or rank of the owner. Fruit-trees would be introduced in appropriate situations for the sake of their fruit, and a choice of odoriferous flowers and shrubs would fringe the margin of the walks, to admit of a more easy inspection of their beauties, and nearer contact of their odors with the olfactory nerves; they would also be disposed in greater profusion, in curious knots or parterres near to the house, or front of the sitting-places or banqueting-rooms. In time, even artificial objects of value, as dials, statuaries, vases, and urns, would be added, in order to create as much variety and interest in a small spot as was consistent with its utility. Such we have found to be the general arrangement of eastern gardens; and as there seems no more obvious way of obtaining the wants of those to whom they belonged, we may pronounce it to be perfectly reasonable and natural.

529. As to the more extensive paradises or parks in which wild beasts were admitted, and even whole regiments exercised, we have but few authentic particulars respecting them. Those of Assyria must be regarded as royal extravagances, calculated to excite astonishment and admiration at their magnitude, and the art and expense employed in their construction; and if any reliance is to be placed in the account given by the ancient authors of the hanging gardens of Babylon, their design will be found singularly to unite this object with the minor beauties of the confined garden; to combine the splendor of magnificence with the delights of the justest feelings of nature. They were situated over, or according to some, adjoining to King Nebuchadnezzar's palace, or on a platform raised
by lofty pillars, on the banks of the Euphrates, in the middle of the city of Babylon. They are said to have contained groves, fountains, and, in short, every object which we have mentioned, as appertaining to the more ordinary description of eastern gardens. Their object was to gratify his Median queen, by that sort of verdant scenery and distant prospect, to which she had been accustomed in the more romantic country of her birth. The height, then, would give that commanding prospect of the water and shipping of the Euphrates, and the city, as well as the gardens within and without its walls, which she particularly desired. The air in that elevated region would be more cool than below; the noise and bustle of the city would cease to be offensive; the whole would be more exposed to breezes and winds; and the mind, deriving so much enjoyment in so singular and elevated a situation, must have experienced emotions at once sublime and romantic. But a faint idea of these gardens will be excited, by imagining the quadrangle of Somerset House crowned with a portion of Kensington gardens; or of the summer garden of Petersburgh placed over the Kremlin in Moscow.

530. How and with what propriety the eastern style came afterwards to be adopted in Greece, Italy, France, and finally in England, is our next enquiry. The principle or instinct of imitation, would be the first cause why the more distant nations, whether colonies from the east, or returning travellers or conquerors, adopted this parent style. This is so obvious, as to require no comment beyond what will be furnished by individual enquiry into our earliest tastes, habits, and predilections in dress, amusements, furniture, and other matters of common life. The next principle is that of use or fitness, which would vary in application, proportionally to the distance and different circumstances of the imitating country. Thus it would not exactly apply in Greece or Italy, where the climate was more temperate, active exercise more congenial, and the habits of the wealthy, for a long time at least, comparatively frugal. Add to this, that verdant landscapes, shade, breezes, hills, waterfalls, and lakes, with their accompaniments of odors, murmurs, singing birds, reflections of objects, were more liberally distributed over the face of general nature. The more active character of man in such countries would, in time, also appropriate to their use from this natural abundance, a greater variety of fruits and legumes.

531. The eastern style assumed a variation in its character under the Romans. The necessarily different culture required for perfecting fruits and culinary vegetables in a different climate, would give rise to the orchard and kitchen-garden. This would simplify the objects of the ornamental garden, which would thus exhibit less a collection of natural beauties, than the display of art, the convenience of taking exercise, here a pleasure rather than a fatigue, and the gratifications of shade, cool breezes, and aromatic odors. A prospect of the surrounding country was desired, because it was beautiful; and where, from various circumstances, it was interrupted by the garden or its boundary fence, mounds or hills of earth were raised, and, in time, prospect-towers appended to the houses. Greater extent would be required for more athletic recreations, and would be indulged in also by the wealth and pride of the owner for obvious reasons. Abridgment of labor would suggest the use of the sheers, rather than the more tardy pruning knife in thickening a row of trees. A row of low trees so thickened, would suggest the idea of a row of clipt shrubs. Hence at first hedges; and subsequently, when art and expense had exhausted every beauty, and when the taste had become tired of repetition, verdant sculpture would be invented, as affording novel, curious, and fantastic beauty, bordering, as do all extremes, upon absurdity. A more extended and absolute appropriation of territory, than what we may suppose to have taken place in the comparatively rude countries of the east, would lead to agricultural pursuits, and these again would give rise to the various arrangements of a Roman country-residence which we know to have existed, and which it would be superfluous to describe. Various other circumstances might be added; but enough has been stated to show that the gardening of the Romans was perfectly natural to them, under the circumstances in which they were placed; it suited their wants, and produced scenes which they found to be beautiful, and was therefore in the justest taste. To have imitated the scenery of nature, or studied picturesque beauty in a garden, would have been merely adding a drop to the ocean of beauties which surrounded them. Expense incurred for this purpose could never have procured applause to the owner, since the more like nature the production, the less would it excite notice. All that was left for man to do, therefore, was to create those beauties of art, convenience, and magnificence, which mark out his dwelling-place, and gratify his pride and taste by their contrast with surrounding nature.

532. The gardening of the Romans was copied in France and Britain, with little variation beyond those dictated by necessity and the difference of climate. It was found to be perfectly beautiful and agreeable; and would have continued to prevail, had Britain continued in similar circumstances to those in which she was at the time of its introduction. But such has been the progress of improvement in this country, that the general face of nature became as it were an ancient garden, and every estate was laid out, bounded, and
subdivided, by stripes of wood, rows of trees, canals, ponds, walls, and hedges. The credit or distinction to be obtained here, by continuing to employ the ancient style, could be no greater than what the Romans would have obtained by imitating nature. In their case all the country was one scene of uncultivated, in ours it was one scene of cultivated, beauty. In this state of things the modern style was adopted, not solely from a wish to imitate the gardening of the Chinese, or a high degree of refinement in taste, but from the steady operation of the same motives which produced and continued the ancient style,—a desire of distinction.

533. The modern style of gardening is unsuitable to countries not generally under cultivation. The English style cannot long please in such countries as Sweden, Poland, and America, otherwise than from its novelty, or as giving rise to certain associations with the people, whose name it bears. What delight or distinction can be produced by the English style in Poland, for example, where the whole country is one forest, and the cultivated spots only so many open glades, with the most irregular and picturesque sylvan boundaries? But let a proprietor there dispose of the scenery around his residence in the Roman or French manner; let him display a fruit or kitchen garden bounded by high stone walls; a farm subdivided by clipped hedges and ditches; and a pleasure-ground of avenues, stars, circles, fountains, statues, temples, and prospect-towers, and he will gratify every spectator. The view of so much art, industry, and magnificence, amid so much wild and rude scenery, awake so many social ideas of comfort and happiness, and so much admiration at the wealth and skill employed, that a mind of the greatest refinement and the justest taste would feel the highest sensation of pleasure, and approve as much of such a country residence in the wilds of Poland or America, as he would of the most natural and picturesque residence of England, amid its highly artificial scenery. Such is the dreariness of the public roads in Poland, Sweden, and Lapland, that the stranger-traveller hails as marks of civilization (fig. 41.) what in cultivated countries would fill his mind with horror.

534. The modern style is not an improvement on the ancient manner, but the substitute of one style for another. Part of the prevailing antipathy to the ancient style proceeds from a generally entertained idea, that the modern is an improvement on it, in the same way as a modern plough is an improvement on the clumsy implements of our ancestors; but the truth is, the two styles are as essentially and entirely different in principle, as painting and architecture, the one being an imitative, and the other an inventive art. The more the ancient style is improved and perfected, the more it will differ from the modern style; and neither improvement nor neglect of the modern style will ever bring it a step nearer the ancient manner.

Landscaping agrees with ancient gardening in no other circumstance than as employing the same materials. It is an imitative art, like painting or poetry, and is governed by the same laws. The ancient style is an inventive and mixed art, like architecture, and governed by the same principles. The beauties which architecture and geometric gardening aimed at, were those of art and utility, in which art was every where awoved. The modern style of gardening, and the arts of poetry and painting, imitate nature; and, in doing so, the art employed is studiously concealed. Those arts, therefore, can never be compared, whose means are so different; and to say that landscape-gardening is an improvement on geometric gardening, is a similar misapplication of language, as to say that a lawn is an improvement of a corn-field, because it is substituted in its place. It is absurd, therefore, to despise the ancient style, because it has not the same beauties as the modern, to which it never aspired. It has beauties of a different kind, equally perfect in their manner as those of the modern style, and equally desirable under certain circumstances. The question therefore is not, whether we shall admit occasional specimens of obsolete gardening, for the sake of antiquity, but whether we shall admit specimens of a different style, from that in general use, but equally perfect in its kind. (Ed. Ence. art. Landscape Gardening.)

535. An enlightened mind will derive pleasure from every style. "When I perceive a man," observes Sir W. Bridges, "incapable of deriving pleasure from more than one style of composition, and dogmatising on its exclusive merit, I pity his weakness and despise his presumption. When he narrows his curiosity, either to what is old or what is new; when he confines his praise, either to the dead or to the living, though in both cases he is ridiculous, perhaps his folly is more evinced in the last." (Censura Literaria, vol. viii. p. 214.) It is the privilege of the man, who has opened to his mind by observation and study all the springs of pleasant association, to delight by turns in the rudeness of solitary woods, in the cheerfulness of spreading plains, in the decorations of refined art, in the magnificence of luxuriant wealth, in the activity of crowded ports, the industry of cities, the pomp of spectacles, the pageantry of festivals. (Ed. Rev. 1806.)

536. We may therefore conclude that gardening, as an art of design, must be considered relatively to the climate and situation of the country, and habits and manners of the
people, where it is employed; and that the ancient and modern styles, viewed in this light, are each perfectly natural, and equally meritíng adoption, according to relative circumstances; less than from any positive beauty or advantages of either manner. We are consequently of opinion, that the ancient style, divested of some ingredients which relate to warm climates, and purified from the extravagances of extremes in decoration, would be in much better taste in some situations in the Highlands of Scotland, and the south of Ireland, than the modern style; and that this style cannot, for a long series of years, afford any other satisfaction in many parts of other countries than what arises from the temporary interest of novelty and accidental association. It may never be altogether lost sight of in subsequent arrangements; but whenever the influence of fashion has subsided, the beauties of the ancient style will be desired, as fulfilling better the objects in view, till landed property, in these countries, becomes enclosed, subdivided, and cultivated, as it is in England.

SECT. III. Of the Climate of Britain, in respect to Gardening.

537. Britain, France, Holland, and the north of Italy, are unquestionably the best countries of Europe for European gardening; and of these, the best parts are such as combine hills and plains, rocks, rivers, and prospects.

538. The preference of Britain, as to government and civilisation, and its equality at least as to soil and surface, will not be disputed. As to climate, Charles II. in reply to some who were reviling it, said, he thought "that was the best climate where he could be abroad in the air with pleasure, or at least without trouble and inconvenience, the most days of the year, and the most hours of the day;" and this he thought could be done in England more than in any other country he knew of in Europe.

539. Gravel and turf. There are, says Sir William Temple, "besides the temper of our climate, two things particular to us, that contribute much to the beauty and elegance of our gardens which are, the gravel of our walks, and the fineness and almost perpetual greenness of our turf. The first is not known anywhere else, which leaves all their dry walks, in other countries, very unpleasant and uneasy. The other cannot be found in France or in Holland as we have it, the soil not admitting that fineness of blade in Holland, nor the sun that greenness in France, during most of the summer; nor indeed is it to be found but in the finest of our soils."

540. Neatness and greenness, says Lord Walpole, "are so essential in my opinion to the country, that in France, where I see nothing but chalk and dirty peasants, I seem in a terrestrial purgatory, that is neither in town nor country. The face of England is so beautiful that I do not believe Tempe or Arcadia were half so rural; for both lying in hot climates, must have wanted the moss of our lawns." (Letters, ed. 1796.)

541. That which prevents the gardening of Britain from attaining to a much higher degree of perfection as an art of taste, is not any natural deficiencies in our climate or soil, nor the want of means to make the most of them, but the want of taste in the proprietors; for after all that has been done and written, there appear to be few who have a just relish for that sort of beauty in pleasure-grounds which is properly called picturesque, or such as a painter might introduce in a picture. We do not allude to any objects or arrangements which would interfere with utility; but to such a disposition of forms as painters call grouping, connection, harmony, and, above all, to that general result which is called unity of expression or character.

PART II.

GARDENING CONSIDERED AS A SCIENCE.

542. Knowledge, in the infancy of every art, is necessarily confined to particulars, but after long observation and experience, the mind begins to generalise facts, and this is the first step towards the foundation of theory, or science; which is nothing more than the substitution of rational principles of action, for habits founded on custom or prejudice. A number of generalised facts accumulated, the next process of the mind is to classify or systematize them; this is the highest effort in the progress of knowledge; and that art will be the most perfectly understood as a science, in which the greatest number of facts, or in other words, the most extensive range of experience and observation, is generalised and arranged in a connected system.

543. Unfortified by the light of science, the practical man has no other assurance for the success of the future, than the experience of the past, and no resource for unforeseen events but ordinary expedients; he resorts to general rules and precepts, which direct what is to be done every where, and on every occasion, instead of applying to principles
for particular instructions, adapted to peculiar cases, or singular purposes. Industry may be baffled, and hope defeated, by a thousand contingencies from causes incident to every process of art or operation of nature. By these the mere routine-practitioner is deranged, or thrown off his guard; whilst the man of science refers events to their true causes, suggests the adaptation of measures to meet every case; and knowing the laws of nature to be immutable, he operates on her materials with confidence in the result.

Science alone, however, without practical experience, will not ensure success, and may at first end in disappointment. But "where theoretical knowledge and practical skill," as D. Stewart observes, "are happily combined in the same person, the intellectual power of man appears in its full perfection, and fits him equally to conduct with a masterly hand the details of ordinary business, and to contend successfully with the untried difficulties of new and hazardous situations." (Elements of the Philosophy of the Human Mind, p. 292. 2d. edit.)

544. The science of every art must necessarily depend on the end or object for which that art is practised; on the nature of the materials employed to procure or attain those ends; and on the name of the agents made use of by human skill to operate on those materials. The object of the art of gardening is twofold: that of cultivating vegetables for use or ornament in domestic or general economy; and that of forming arrangements of external scenery, beautiful as such, and suitable for personal recreation. The first object, therefore, to be ascertained on this subject, should be the wants, desires, and taste of that society for which the gardening is intended; the second, the study of the vegetable kingdom; the third, the study of the natural agents of garden-culture; the fourth, that of the artificial agents of garden-culture; and the fifth, that of the operations of garden-culture. All the operations of territorial cultivation are either mechanical or chemical; and must therefore depend on the laws which govern the common materials of our globe. Those laws, or the manner and circumstances in which these materials operate on each other, constitute the limit of human science; for any attempt to go farther and discover first causes, inevitably ends in disappointment.

The first branch of the science of gardening, or the study of society and taste, may be considered as ascertained by every individual, from his own observation and experience; that is, from the circumstance of his being himself a specimen of the society for the time being. This branch, therefore, does not require farther consideration in a work like the present.

The second and third branches, in which gardening is considered as a science of chemical agencies, are important subjects of study, and admit of much improvement; though unquestionably considerable progress has been made within the last fifty years, since the study of vegetable physiology and chemistry have become more general; and since these arts have been enriched by the discoveries of Mirbel, Keyser, Knight, Le Naitre, Chaplet, and Davy; and applied to agriculture and horticulture by Davy and Knight, in England, and Du Hamel, Thouin, and others, in France.

The fourth and fifth branches, in which gardening is considered as a science of mechanical operations, may be said to have partaken of the general progress of the age, and to have adopted various improvements made in architecture and engineering, in so far as they were found applicable to either its useful or agreeable destinations. Here, however, there is still great room for advancement, especially in the construction of hot-houses, and the formation of walled gardens.

The last branch, in which gardening is considered as a science of design and taste, is founded on principles common to other arts, as to architecture and landscape-painting, whose ends are similar; and here, though its science has long been as much neglected as in the other branches, yet now it may be considered to be fully ascertained and fixed by Alison, Cowley, and Price; and applied by Wheatley and Price, in England, and Girardin and De Lâse, in France.

545. To know the science of any one art perfectly, would require a knowledge of all the others which bear relation to it, or serve in any way to explain the nature and influence of its operations and arrangements. But this is more than can be expected from men in general (Aubert, in his Cours de Physiologie, Paris, 1816, gives a table of twenty sciences as related to Botany alone); what cannot be hoped for from practical men; and what would require in a systematic view of gardening like the present, treatises on most of the other arts. It is preferable, in our opinion, to draw from other branches of knowledge, the explanations which they afford of particular operations or phenomena, that come into notice in discussing what we have laid down as leading principles of gardening. Thus, in place of treating of chemistry, we have merely drawn from that science what belongs to the study of vegetables, soils, and manures, &c.; instead of a treatise on the mechanical powers, we have merely given an explanation of the principles on which each class of implements and machines operates; and in place of treating of architecture and painting, we have merely discussed the subject of design and composition in these arts; the first as applicable to buildings and artificial dispositions of ground, and the second as directing the formation of real scenery.

BOOK I.

THE STUDY OF THE VEGETABLE KINGDOM.

546. Organised bodies are divided into two orders; those endowed with sentiment, or a consciousness of their existence, and those deprived of that sensibility. The study of
the former is designated zoology; that of the latter, botany or phytology. In the latter science, modern botanists have introduced the following subdivisions: 1. Systematic botany; in which plants are studied apart, as distinct beings, and considered in respect to their resemblances, differences, nomenclature, and classification. 2. Vegetable anatomy and physiology; or the study of plants as living beings, in which is considered the form of their organs, and their mode of nourishment and of multiplying themselves. 3. Botanical geography; in which plants are considered relatively to climate, surface, soil, country, habitation, &c. 4. Applied botany; in which vegetables are considered with respect to the wants of man and other animals; and which includes the study of the medical and economical properties of plants; the means by which man procures such as he wants, either by searching for them in a wild state or by cultivation. This last department of the science may be considered as including agriculture and gardening; but these are parts of it so vast and important as to form separate branches of study. Conformably to this view of the subject, we have here considered the study of plants as to history, glossology, phytography, taxonomy, anatomy, chemistry, physiology, pathology, geogrophy, and culture.

CHAP. I.

Origin, Progress, and present State of the Study of Plants.

547. The study of plants may be regarded as coeval with the creation of man, because they are in a great measure indispensable to the support of animal life. The first stage in the progress of this study would be that in which the attention of the human mind was directed to the discrimination of spontaneous vegetables, as fit for food. A second stage, that in which men began to direct their attention to useful vegetables, as capable of furnishing, by means of cultivation, an increased supply proportioned to the wants of population. Then it was that agriculture, in the proper sense of the word, would commence in society. A third stage was that in which plants began to be regarded as furnishing not only necessities, but comforts; and from this period, whenever it happened, may be dated the origin of horticulture. A fourth stage was that in which plants began to be considered as furnishing, not merely comforts, but luxuries. Odors and beautiful flowers would be prized; and hence the origin of horticulture.

In taking a rapid view of the progress of the study of plants among the ancients and moderns, we pass over the fabulous history of the Greeks, and commence with Solomon, who appears to have written a treatise on vegetables somewhere about the year B. C. 1004. This work is lost; and the next name in order is Thales, in B. C. 604. To him succeeded the celebrated Pythagoras, about B. C. 530, who is believed to have prohibited his disciples the use of leeks, on account of a supposed identity of origin between leeks and human flesh. He is also said to have written a treatise on onions. Anaxagoras, another Greek philosopher of this period, maintained that the seeds of all vegetables are lodged in the atmosphere; from whence they descend, along with the rain, to the earth, where they connect with the soil, and spring up into plants. Empedocles is said to have attributed sexes, desires, and passions to plants; and Democritus wrote a treatise on their smells. Hippocrates, about the year B. C. 406, introduced a new and enlightened system of medical study, a subject intimately connected with that of plants; and his contemporary, Crates, wrote a book on botany, of which some fragments lately existed in the imperial library at Vienna. Aristotle, about B. C. 350, wrote a scientific work on plants, which, though also lost, is quoted by contemporaries, and has thus obtained for its author the title of father of natural history, as well as prince of metaphysicians. His Discourses on Sophocles, about B. C. 280, was written on plants; he described 500 species, and endeavours to account for the phenomena of vegetation.

Soon after Theophrastus, the Greek empire began to decline, and with it the study of plants. Botany, with the other arts and sciences, migrated to Italy, in which it made some progress, as we may see by the writings of Pliny, Virgil, and other geographical authors of the Augustan age. Those Roman writers, however, that can be considered strictly botanical, are only Dioscorides and Pliny. The work of the former, a body of materia medica; that of the latter, Rousseau considers as a body of receipts. Nothing is known of the state of botany during the dark ages.

On the revival of the arts in the beginning of the fifteenth century, one of the first fruits it produced was the introduction of figures from wooden cuts, by Brunsfelsius of Mayence, in Germany. His Histora Plantarum, published in the beginning of the sixteenth century, excited the emulation of other botanists; and plans at Augsburg, Cordus, Fussellius, Dorenceu, and Chloanis. Matthioli was the first Italian, Delachamp and Baulin the first Frenchmen, and Turner and Gerarde the first Englishmen who caught the flame.

But though prints had been introduced, method was wanting, without which all study of natural history must be of the most imperfect and limited kind. Gesner, a native of Zurich, in Switzerland, made the first attempt at arranging plants into classes, orders, and genera, about the middle of the sixteenth century. Cesalpinus, a native of Tuscany, presented a similar arrangement at the same time: growing any thing of that of Gesner: a common occurrence in the history of inventions, and a proof that the general state of botanical science rendered such an invention necessary. After this period the study of botany proceeded with rapid strides; and herbariums and copper-plates of plants were invented by Columbus of Naples.

Botanic gardens were established about the middle of the sixteenth century, first in Italy (90), in 1558, and afterwards in France (583), Germany (216), and England (372), before the completion of the sixteenth century. This circumstantial contributed, in an astonishing degree, to the progress of the study of plants, and procured the patronage of the wealthy.

Botany declined or was stationary, for the greatest part of the sixteenth century; but revived, owing, as it is thought, to a new direction given to the spirit of philosophical enquiry, by the illustrious Bacon. This wonderful philosopher explored and developed the true foundations of human knowledge, with a sagacity and penetration unparalleled in the history of mankind. He dared to disengage himself from the fetters of academical authority, condemned the visionary speculations of the schools, and recommended the substitution of analytical and inductive investigation, proclaiming truth to be but the image of nature.
The structure of plants, and the phenomena of vegetable life, began to attract attention in the seventeenth century, 300 years after it had been first attempted by Theophrastus. Malpighi, an Italian, and Grew, an Englishman, carried on this study at the same time, unknown to each other; the result of their investigations were communicated to the scientific world, towards the end of the seventeenth century, removing in great part the veil which had hitherto enveloped the phenomena of vegetation. The plan which these philosophers pursued, was that of experiment recommended by Bacon; the result may be mentioned as the first fruits of his philosophy.

548. About the end of the seventeenth and beginning of the eighteenth century, different methods or systems for arranging and naming plants were produced by Herman and Boerhaave, of Leyden; Rivinus and others, in Germany; Tournefort and Magnol, in France; and Morrison and Ray, in England. Of these systems and nomenclatures, that of Tournefort was the most generally followed, of which we may give, as an instance, the first six editions of Miller's Gardener's and Botanist's Dictionary. Tournefort's system depended chiefly on the corolla; but when the plants of America began to be introduced, to them it was found impracticable in its application. All the other methods were in different degrees defective, and it was not till the appearance of Linnaeus that this perplexity was removed.

549. Linnaeus founded what is called the sexual system, deducing his rules of method from incontrovertible principles; establishing, in his Philosophica Botanica, laws of generic and specific distinction, and rules of legitimate definition. This simplicity of system, perspicuity of arrangement, and precision of language, has elevated botany to the high rank it now holds in the scale of human science; allured to the study of plants men of the most distinguished abilities; and excited that ardor for botanical investigation which characterises the present age. This new system, as founded on the sexes of plants, naturally led Linnaeus to the study of the structure and phenomena of vegetables, and this effected at last a close and intimate union between systematic and physiological botany. The propriety and advantage of this union are evident, since a thorough knowledge of plants involves both studies. The doctrines of Linnaeus soon procured followers in every country; but the most distinguished of his immediate disciples, were Kalm, Hasselquist, Læfing, and Koening, all of whom travelled in pursuit of new plants, under the auspices of their great master. Of his more remote disciples, may be named as most distinguished, Gmelin, Oeder, Hedwig, Gartner, Lamareck, and Sir James Edward Smith, the founder and president of the Linnean Society of London, and proprietor of the whole of the Linnean Herbarium; from whose meritorious labors, botany has derived and is still deriving important advantages.

The study of physiological botany, however, was less attended to than that of methodical arrangement by Linnaeus and his immediate disciples; and indeed, it would have been too much to have expected an equal progress in both, by him who had made so astonishing an improvement in the one department. To the names of Grew and Malpighi, in physiological botany, may be added, in addition to that of Linnaeus, Hales, Bonnet, Du Hamel, Hedwig, Spallanzani, and especially Priestley. This philosopher first brought the aid of pneumatic chemistry to this study, which, under the direction of such men as Ingenhouse, Schebier, and Sassaure, has done more to illustrate the phenomena of vegetation, than all the other means of investigation put together. If we add to these the ingenious hints and speculations of Darwin, in his Botanic Garden, and in Physiologia; the masterly experiments of Knight, given in the Philosophical Transactions; the vegetable physiology of Mirbel and Keyser; with the philosophical and systematic view of the whole subject, by Keith, in his Introduction to Vegetable Physiology; we may assert with the latter writer, that our knowledge of the physiology of vegetables, may now be regarded as resting upon the foundation of a body of the most incontrovertible facts, and assuming a degree of importance inferior only to that of the physiology of animals." Such may be considered the present state of physiological botany.

550. The chief improvement which has been made in the systematic department since the days of Linnaeus, consists in the approximations that have been made to a method of arrangement, founded on a more extended view of the relations of plants than is taken in the Linnean, or artificial system. By this system, which is designated natural, as founded on the whole of the natural properties of the plant, the vegetable kingdom is thrown into groups, and whoever knows any one plant in that group, will have some general idea of the appearance and qualities of the whole. The use of such a classification for such as already know plants individually, is therefore obviously great, though for discovering the names of particular species, it is in its present state less convenient than the Linnean system, for owing to the small number of plants which are yet known to botanists, the groups or classes of the natural method are far from being perfect.

551. The first scheme for a natural method of arranging plants was communicated to the public by Linneus in his Fragments of a Natural Method, published in 1738. The next person who successfully traced the affinities of plants, was B. Jussieu, of Paris. In 1759, he displayed his method in the arrangement of the plants in the royal gardens of Triannon, near Paris. Afterwards, Michael Adamson, a pupil of Jussieu, who had travelled through part of Africa, examined all the published systems, and paid the greatest attention to the natural affinities of vegetables, published a very learned and useful work, Familles des Plantes, in 1763. But it is to A. L. Jussieu, of the National Institute, nephew of the elder Jussieu, that the science of natural affinities owes most; and his Genera Plantarum, published in 1789, is considered the most learned botanical work that has appeared since the Species Plantarum of Linneus, and the most useful to those who study the philosophy
of botanical arrangement." Ventenat has lately published a commentary on the writings of A. L. Jussieu; and this author himself is now publishing a Species Plantarum, arranged according to his method. Professor Decandolle, of Geneva, considered one of the first French botanists, is also a follower of this system, in which he has made some improvements (Theorie de la Botanique, 1817); and he also is occupied with a Species Plantarum, arranged according to his own improvements.

552. Botanical geography, or the knowledge of the places where plants grow (habitationes plantarum), and the causes which influence their distribution over the globe, was totally neglected by the ancients. Clusius is the only botanist who before the eighteenth century took any pains to indicate the native countries of plants. Bauhin and Tournefort often neglected it. Linnaeus is the first who gave the idea of indicating it in general works on botany, and his Floras of Sweden and Lapland are models of their kind in this respect. Since this period many excellent Floras have appeared, among which the Flora Britannica, by Sir J. E. Smith, and the Flora Francaise, by Professor Decandolle, may be mentioned as examples. The first grand effort at generalising the subject, was made by Humboldt, in his Essai sur la Geographie des Plants, &c. 1811. This essay is rich in facts, and filled, like all the works of this philosopher, with new and ingenious views of nature. In a subsequent work, De Distributione Plantarum, 1815, he has more especially examined the influence of elevation of surface on vegetation. Professor Decandolle, has also given some views relatively to the subject, in his Flora Francaise, and R. Brown, one of the first botanists in this country, in Remarks on the Botany of Terra Australis, and on the Plants of Congo. On the whole, however, this branch of botany, the most important for agriculture and gardening, and without some knowledge of which, naturalisation, and even culture, must go on by mere hazard, may be regarded as still in its infancy.

553. With respect to applied botany, its history would involve that of medicine, agriculture, gardening, and other mixed and mechanical arts. Plants, it may be observed, have in every age but the present, formed the chief articles of the materia medica of all countries. At present the mineral kingdom is chiefly resorted to by the practitioners of the healing art in Europe; but plants retain their ground in other countries; and fashion, which enters into every thing, may change, after exercising a certain degree of influence. The universal use of the vegetable kingdom in the dietetics of every country; in the arts of clothing, architecture, and, in short, in almost every branch of industry, need not be enlarged on.

554. Fossil botany, as studied from the impressions of plants found in the secondary strata of the earth, has only lately begun to attract attention; but the essays of Schlotthheim, Knor, Martin, Faujas de St. Fond, and Parkinson's Essay on Organic Remains, deserve to be mentioned.

Chap. II.

Glossology, or the Names of the Parts of Plants.

555. All the arts and sciences require to express, with brevity and perspicuity, a crowd of ideas unused in common language, and unknown to the greater part of men. Whence that multitude of terms, or technical turns, given to ordinary words which the public turn often into ridicule, because they do not feel the use of them, but which all those are obliged to make use of, who apply themselves to any study whatever. Botany having to describe an immense number of beings, and each of these beings having a great variety of organs, requires a great variety of terms. Nearly all botanists are agreed as to these terms; and in order that they may be universally understood and remain unchanged in meaning, they are taken from a dead or fixed language.

556. A plant in flower, surveyed externally, may be perceived to be composed of a variety of obvious parts, such as the root, the stem, the branch, the leaf, the flower, the fruit, and perhaps the seed; and other parts less obvious, as buds, prickles, tendrils, hairs, glands, &c. These, with their modifications, and all the relative circumstances which enter into the botanical description of a plant, form the subject of glossology, the details of which, involving the definition of some hundreds of terms, are here omitted; because to those conversant with them it would be of little use, and those who have them still to learn will find it more convenient to have recourse to some elementary work, where most of them are illustrated by figures. (See Smith's Introduction to Botany, Grammar of Botany, and similar works.)
Chap. III.

Phytography, or the Nomenclature and Description of Plants.

557. The whole vegetable kingdom is divided into classes, orders, genera, species, and varieties. A class is distinguished by some character which is common to many plants; an order is distinguished by having some character limited to a few plants belonging to a class; a still more limited coincidence constitutes a genus; and each individual of a genus, which continues unchanged when raised from seed, is called a species. A variety is formed by an accidental deviation from the specific character, and easily returns by seed to the particular species from which it arose.

558. Before botany became a regular science, plants were named as individual beings, without regard to any relation which they had to one another. But from the great number of names to be retained on the memory, and the obvious affinities existing among certain individuals or natural families, some method was soon found necessary, and it was then deemed requisite to give such composite names as might recall to mind something of the individuals to which they were applied. Thus we have *Anagallis flore caruleo*, *Mesplius oculata pyrifolia*, &c. But in the end the length of these phrases became inconvenient; and Linnaeus, struck with this inconvenience, proposed that the names of plants should henceforth consist of two words only, the one the generic or family name, and the other the specific or individual name.

559. The names of classes and orders were originally primitive, or without meaning, as the Grasses of Tragus, *Poppies* of Bauhin, &c.; and afterwards so compounded as to be long and complex, as the *Polyplostemonopetale*, *Eufthionmacrastemones*, &c. of Wachendorff. Linnaeus decided, that the names of classes and orders should consist of a single word, and that word not simple or primitive, but expressive of a certain character or characters, found in all the plants which compose it.

560. In applying the names to plants, three rules are laid down by botanists: 1st, That the languages chosen should be fixed and universal, as the Greek and Latin; 2d, That these languages should be used according to the general laws of grammar, and compound words always composed from the same language, and not of entire words, &c.; 3d, That the first who discovers a being, and enregisters it in the catalogue of nature, has the right of giving it a name; and that that name ought to be received and admitted by naturalists, unless it belong to a being already existing, or transgress the rules of nomenclature. Every one that discovers a new plant may not be able to enregister it according to these laws, and in that case has no right to give it his name; but the botanist who enregisters it, and who is in truth the discoverer, may give it the name of the finder, if he chooses. We shall notice this subject in the order of names of classes and orders, of genera, of species, of varieties and sub-varieties, descriptions of plants, dried plants or herbariums, and methods of study.

Sect. I. Names of Classes and Orders.

561. The names of the classes and orders of Linnaeus and Jussieu, being exclusively used at the present time, we shall pass over those of the earlier botanists.

562. The names of the Linnean classes and orders are, as far as practicable, expressive of some common character belonging to all the plants which compose them, and consist only of one word for the class, and another for the order, both compounded from the Greek. There are exceptions, however, to the first rule in several of the classes of the sexual system, as in *Icosandria*, *Monodia*, *Diecia*, which contain plants that have not the circumstances expressed in the title. Richard (Nouv. Elem. de Bot. 1819) has given some new names, which he proposes to substitute for the least perfect of those fixed on by Linnaeus, but they are not likely to be generally received, at least in this country.

563. The names of natural orders may be taken from such genera as may serve to recall the general relations of each tribe or order. The name of the order and generic name, however, are at no time to be precisely the same; from the manifest impropriety and confusion of arranging a thing under itself. Thus in the natural method of Linnaeus, the order *Palmae* has no genus of that name. In the method of Jussieu, the name of an order is composed from the name of one of the most characteristic genera of that order, as *Rosaeae*, a natural order of dicotyledonous plants, containing the well known genus *Rosa*, &c.; and while the name of an order is terminated by two syllables, that of a sub-order is terminated by one only; as *Rosaceae*, *Rosa*; *Ranunculaceae*, *Ranunculus*.

Sect. II. Names of Genera.

564. Names from the Greek or Latin are exclusively admitted by modern botanists, all others being esteemed barbarous. Without this rule we should be overwhelmed, not only
with a torrent of uncouth and unmanageable words, but we should be puzzled where to fix our choice, as the same plant may have fifty different original denominations in different parts of the world, and we might happen to choose one by which it is least known. There are however some exceptions, such as 

Acaia, Alisma, which are of Celtic origin, and Årvo, Alehemilla, derived from the Arabic.

565. Such names as indicate some striking peculiarity in the genus are to be preferred: as Glycyrrhiza, a sweet root, for the liquorice; Amaranthus, without decay, for an everlasting flower; Helianthus, a sun-flower; Lithospermum, a stony seed; Eriocaula, a flower with a singularly woolly base or cup; Origanum, an ornamental mountain plant; Hemerocallis, beauty of a day; Arenaria, a plant that inhabits sandy places; and Gypsophila, one that loves a chalky soil. Such as mark the botanical character of the genus, when they can be obtained for a nondescript plant, are peculiarly desirable; as Ceratopotamus, from the branched horn-like petals; Lasiospatulum, from the very singularly woolly corolla; Calceolaria, from the shoe-like figure of the same part; Conchiun, from the exact resemblance of its fruit to a bivalve shell.

566. To dedicate certain plants to the honor of distinguished persons has been customary in all ages. Thus Euphorbia commemorates the physician of Juba a Moorish prince, and Gentiana immortals a king of Illyria. The scientific botanists of modern times have adopted the same mode of preserving the memory of benefactors to their science; and though the honor may have been sometimes extended too far, that is no argument for its total abrogation. Some uncouth names thus unavoidably deform our botanical books; but this is often effaced by the merits of their owners, and it is allowable to model them into grace as much as possible. Thus the elegant Tournefort made Gnidella, from Gundelsheimer; which induced Sir J. E. Smith to choose Goodenia, for his friend Dr. Goodenough, though it has, when too late, been suggested that Goodenovia might have been preferable. Some difficulty has arisen respecting French botanists on account of the additional names by which their grandeur, or at least their vanity, was displayed during the existence of the monarchy. Hence Pittonia was applied to the plant consecrated to Pitton de Tournefort; but Linnaeus preferred the name by which alone he was known out of his country, or in learned language, and called the same genus Tournefortia.

567. A fanciful analogy between botanists and the plants named after them has been made by Linnaeus in the Critica Botanica. Thus Bauhinia, after the two distinguished brothers John and Gaspard Bauhin, has a two-lobed or twin leaf. Scheuchzeria, a grassy Alpine plant, commemorates the two Scheuchzers, one of whom excelled in the knowledge of Alpine productions, the other in that of grasses. Dorstenia, with its obsolete flowers, devoid of all beauty, alludes to the antiquated and uncouth book of Dorstenius. Hernandia, an American plant, the most beautiful of all trees in its foliage, but furnished with trifling blossoms, bears the name of a botanist highly favored by fortune, and allowed an ample salary for the purpose of investigating the natural history of the Western world, but whose labors have not answered the expense. On the contrary, Magnolia, with its noble leaves and flowers, and Didenia, with its beautiful blossoms and fruit, serve to immortalize two of the most meritorious among botanists. Linnea, a depressed abject Lapland plant, long overlooked, flowering at an early age, was named by Gronovius after its prototype Linnaeus.

Sect. III. Names of Species.

568. Specific names should be formed on similar principles to the generic ones; but some exceptions are allowed, not only without inconvenience, but with great advantage. Such as express the essential specific character are unexceptionable, as Banksia serrata, integrifolia, dentata, &c.; but perhaps those which express something equally certain, but not comprehended in that character, are still more useful, as conveying additional information, like Ixora alta and cocicina, Seleranthus annuus and perennis, Alantis fragans, Saxifraga cerna, &c.; for which reason it is often useful, that vernacular names should not be mere translations of the Latin ones. Comparative appellations are well, as Banksia ericifolia, Andromeda salicifolia, Saxifraga bryoides, Milium cimicinum, Elymus Hystris, Pedicularis Sceptrum. Names which express the local situations of different species are excellent, such as Metapnypinus arvense, pratensis, nemorosum and sylvaticum, Carex arenaria, alpina and sylvatica, as well as aquatica, maritima, rupestris, alpina, nivalis, used for many plants. But names derived from particular countries or districts are liable to much exception, few plants being sufficiently local to justify their use. Thus Ligusticum cornubium is found not only in Cornwall, but in Portugal, Italy, and Greece; Schwenkia americana grows in Guinea as well as in South America. Such therefore, though suffered to remain on the authority of Linnaeus, will seldom or never be imitated by any judicious writer, unless Trollius europaeus and asiaticus may justify our naming the third species of that genus, lately brought from America, americanus. The use of a plant is often commodiously ex-
pressing in its specific name, as *Brassica oleracea*, *Papaver somniferum*, *Inocarpus edulis*; so is likewise its time of flowering, as *Primula veris*, *Leucojum vernum*, *estivum*, and *autumnale*, and *Helleborus hyemalis*.

569. When a plant has been erroneously made a distinct genus, the name so applied to it may be retained for a specific appellation, as *Lathyrus Phylgatea*, and *Bartsia Gynandra*; which may also be practised when a plant has been celebrated, either in botanical, medical, or any other history, by a particular name, as *Origamum Dictamnus*, *Artemisia Dracunculus*, *Laurus Cinnamomum*, *Selium Carefola*, *Curca Papaya*. In either case the specific name stands as a substantive, retaining its own gender and termination, and must begin with a capital letter.

570. A specific name is occasionally adapted to some historical fact belonging to the plants or to the person whose name it bears, as *Linnæa borealis*, from the great botanist of the north; *Mararea exoticar*, after one of his favorite pupils, a foreigner; *Brownilla donnissa et elata*, from a botanist of humble origin and character, who afterwards became a lofty bishop. In like manner *Buffyonia tennifolia*, is well known to be a satire on the *slender* botanical pretensions of the great French zoologist.

571. Names sanctioned by general use are for the most part held sacred among botanists. The study of natural history is, from the multitude of objects with which it is conversant, necessarily so encumbered with names, that students require every possible assistance to facilitate the attainment of those names, and have a just right to complain of every needless impediment. The names established throughout the works of Linnaeus, are become current coin, nor can they be altered without great inconvenience. Those who alter names, often for the worse, according to arbitrary rules of their own, or in order to aim at consequence, which they cannot otherwise attain, are best treated with silent neglect. When, however, solid discoveries and improvements are made in the science; when species or genera have been confounded by Linnaeus himself, and new ones require to be separated from them, the latter must necessarily receive appropriate apppellations; as also when a totally wrong and absurd name has by mistake been given, as *Begonia capensis*. In such cases names must give place to things, and alterations proceeding from such causes must be submitted to. (Smith’s Introduction, ch. 22.)

**Sect. IV. Names of Varieties and Subvarieties.**

572. The names which botanists give to varieties are of the simplest description; they always convey an idea of the variation which has taken place, and are used in addition to the specific name. Thus we have *Caltha palustris*, the species, and *palustris flor*; *pleno*, the double-flowered *caltha*, &c. As a series of species are commonly numbered 1, 2, 3, &c. so the varieties of a species, are generally, for distinction sake, designated by the letters of the Greek alphabet, thus: *Brassica oleracea*, the species; *α. Capitata*, the first species; *β. Rubra*, the second species; *γ. Sabellica*; *δ. Sabellicca*, &c.

573. Subvarieties of plants are accidental modifications of varieties of a very temporary and fluctuating nature. They are generally produced by culture, and are more especially known in garden-fruits, culinary vegetables, and what are called florists’ flowers. The differences among subvarieties are generally so slight, or so difficult to define, as not to admit of the application of scientific names. Botanists, therefore, pay no attention to them; but gardeners, to whom they are of considerable importance, have found it necessary in some way or other to distinguish them, and they generally apply the name of the person or place, by whom or where, they were originated. Thus *Pyrus malus* is the crab or apple, *P. malus var. domestica*, the cultivated apple. *Pyrus malus var. domestica subvar. Downton pippin*, apple raised from seed at Downton. *P. in v. d. subvar. Kirk’s fame*, &c. *Brassica oleracea var. capitata*, common white cabbage. *B. o. var. c. subvar. Battersea early common cabbage*, an early variety raised at Battersea. *Dianthus caryophyllus* is the clove pink. *B. c. var. flore pleno* is the carnation. *Dian. cary var. fl. pl. subvar. Hogg’s seedling*, a variety of carnation raised by Hogg. *D. c. fl. pl. subvar. Lady Jane Grey*, a variety of carnation named after Lady Jane Grey. A refinement on this sort of nomenclature consists in adding the name of the person who originated the subvariety, to the name of the person or place after whom or which it was named; thus, *Hogg’s Lady Jane Grey*, Duncan’s Cheshire hero, &c. “To raise a fine new variety of any florist’s flower, to name it after some great personage, and with that name to couple your own, is the greatest honor, says Emmerton (Treatise on the Auricula), which a florist can aspire to.”

574. Names of subvarieties which indicate something of their properties are to be preferred, as Black July-grape, June-eating-apple, &c.; or such as indicate the place or time or where they were originated or abroad, as D.splitext onion, Claremont nupitals primrose, or the Afflicted queen carnation. Such names convey ideas which may prove useful as to the qualities of the variety; thus the first and second names convey some idea of the time of ripening; the third, some idea of the soil and climate in which the plant thrives; the fourth and fifth, the date, and consequently the age of the variety.
Sect. V. Descriptions of Plants.

575. Plants are described by the use of language alone, or by language and figures, models, or dried plants conjointly. The description of plants may be either abridged or complete. The shortest mode of abridgment is that employed in botanical catalogues, as in those of Donn or of Sweet. A complete description, according to Decandolle, ought to proceed in the following order:

1. The admitted name.
2. The characteristic phrase.
3. The synonyms.
4. The description, comprehending the organs, beginning with the root.
5. The history, that is, the country, data
6. Application, which includes the culture or the uses.
7. Critical or incidental observations.

576. Descriptions are, in general, written in Latin, the names in the nominative, and followed by epithets which mark their modifications, and which are not united by a verb, unless that becomes necessary to explain any circumstance which is not provided for in the ordinary form of the terms. Doubts as to the received ideas on the plant described, or any other miscellaneous matters, are to be placed under the last article.

577. Collections of botanical descriptions may be of different sorts, as

1. Monographs, or descriptions of one genus, tribe, or class, as Lindley's Monographia Boraeana.
2. Floras, or an enumeration of the plants of any one district or country, as Smith's Flora Britannica.
3. Gardens, or an enumeration, descriptive or nominal, of the plants cultivated in any one garden, as Aiton's Hortus Kewensis.
4. General works, in which all known plants are described, as Willdenow's Species Plantarum, and Persoon's Synopsis Species Plantarum.

All these classes of books may be with or without plates or figures; and these again, may be of part of the whole plant, and colored or plain, &c. Some botanists have substituted dried specimens for figures, which is approved of in cases of difficult tribes or genera; as in the grasses, ferns, geraniaceae, ericaceae, &c.

578. Collections of descriptions of plants in what are called gardens or catalogues, form one of the most useful kinds of botanical books for the practical gardener. The most complete of these hitherto published is the Hortus Suburbannus Londinensis of R. Sweet; but this, as well as all other works of the kind, admit of being rendered much more descriptive by a more extensive use of abbreviated terms, and even by the use of pictorial signs. (fig. 42.) Sweet's Hortus gives the Linnean and natural class and order, systematic and English name, authority, habitation in the garden, time of flowering, year of introduction, and reference to engraved figures; but there might be added on the same page, the height of the plant, color of the flower, time of ripening the seed or fruit, soil, mode of propagation, and the natural habitation of such as are natives. Instead of the usual mark (n) for a ligneous plant, pictorial types might be introduced to indicate whether it was a tree or shrub, deciduous or ever-green, spiny topt, a palm, climbing, twining or trailing, &c.; and instead of the common sign for a perennial (t), biennial (d), or annual (o), something of the natural character of the plant might be similarly indicated. A single line of a catalogue formed on this principle would expand into a long paragraph of ideas in the mind of the botanist or gardener, and might easily be rendered a Species Plantarum, by introducing short specific characters in single lines on the page opposite the catalogue lines, as in Galpine's Compendium of the British Flora. It might farther, by subjoining notes to all the useful or remarkable species at the bottom of every page, be rendered a history of plants, including their uses in the arts and manufactures, and their culture in agriculture or gardening. Such an Encyclopedia of Plants, with other improvements, we, with competent assistance, have sometime since commenced, and hope soon to submit to the public.
FORMATION and preserving Herbariums.

579. Dried plants far surpass either drawings or descriptions in giving complete ideas of their appearance. When plants are well dried, the original forms and positions of even their minutest parts, though not their colors, may at any time be restored by immersion in hot water. By this means the productions of the most distant and various countries, such as no garden could possibly supply, are brought together at once under our eyes, at any season of the year.

580. The mode or state in which plants are preserved, is generally desiccation, accompanied by pressing. Some persons, Sir J. E. Smith observes, recommend the preservation of specimens in weak spirits of wine, and this mode is by far the most eligible for such as are very juicy; but it totally destroys their colors, and often renders their parts less fit for examination, than by the process of drying. It is, besides, incommmodious for frequent study, and a very expensive and bulky way of making an herbarium.

581. The greater part of plants dry with facility between the leaves of books, or other paper, the smoother the better. If there be plenty of paper, they often dry best without shifting; but if the specimens are crowded, they must be taken out frequently, and the paper dried before they are replaced. The great point to be attended to is, that the process should meet with no check. Several vegetables are so tenacious of their vital principle, that they will grow between papers; the consequence of which is, a destruction of their proper habit and colors. It is necessary to destroy the life of such, either by immersion in boiling water, or by the application of a hot iron, such as is used for linens, after which they are easily dried. The practice of applying such an iron, as some persons do, with great labor and perseverance, till the plants are quite dry, and all their parts incorporated into a smooth flat mass is not approved of. This renders them unfit for subsequent examination, and destroys their natural habit, the most important thing to be preserved. Even in spreading plants between papers, we should refrain from that precise and artificial disposition of their branches, leaves, and other parts, which takes away from their natural aspect, except for the purpose of displaying the internal parts of some one or two of their flowers, for ready observation. The most approved method of pressing is by a box or frame, with a bottom of cloth or leather, like a square sieve. In this, coarse sand or small shot may be placed, in any quantity. Very little pressing is required in drying specimens; what is found necessary should be applied equally to every part of the bundle under the operation, and this can only be done by the use of an equalising press of granulated matter, of compressed air, or of a bag of water.

Dried specimens are kept in herbariums in various ways: sometimes loose between leaves of paper; at other times wholly gummed or glued to paper, but most generally attached by one or more transverse slips of paper, glued on one end and pinned at the other, so that such specimens can readily be taken out, examined, and replaced. On account of the aptitude of the leaves and other parts of dried plants to drop off, we glue them entirely, and such seems to be the method adopted by Linnaeus, and recommended by Sir J. E. Smith. "Dried specimens," the professor observes, "are best preserved by being fastened, with weak carpenter's glue, to paper, so that they may be turned over without danger. Thick slips of paper are to be used to bind them more firmly down. A half sheet, of a convenient folden size, should be allotted to each species, and all the species of a genus may be placed in one or more whole sheets or folios. On the outside of the latter should be written the name of the genus, while the name of each species, with its peculiarity, its growth, times of gathering, the finder's name, and any other concise piece of information, may be inscribed on its appropriate paper. This is the plan of the Linnaean herbarium."

In arranging dried specimens, the most simple and obvious guide is that of the order of their flowering, or that in which they are gathered, and this may be adopted during the summer season; but afterwards they ought to be put into some scientific method, either natural or artificial. They may be kept in a cabinet, consisting of a collection of drawers for each order; and the relative as well as absolute size of these drawers, will depend on the proposed extent of the collection, as whether of British plants only, of hardy plants only, or of all plants introduced to this country. In the chapter on vegetable geography will be found data for the size of the drawers under every case. The fungi cannot in general be dried so as to retain the habit and character of the vegetating plant; but this defect is supplied by models, of which excellent collections are prepared for sale by the Sowerby family, well known for their botanical works.

The perfect preservation of an herbarium is much impeded by the attacks of insects. A little beetle, called Piusius far, is more especially the pest of collectors, laying its eggs in the gourds or receptacles of flowers, as well as on the more solid parts, which are speedily devoured by the maggots when hatched, and by their devastations, paper and plants are alike involved in ruin. The most bitter and acrid tribes, as euphorbia, gentiana, prunus, the synngenes, class, and especially willows, are preferred by these vermin. The last mentioned only can scarcely be thoroughly dried before it is devoured. Ferns are scarcely ever attacked, and grasses but seldom. To remedy this inconvenience, a solution of corrosive sublimate of mercury in rectified spirits of wine, about two drams to a pint, with a little camphor, will be found perfectly efficacious. It is easily applied with a carpenter's brush, when the specimens are perfectly dry, in a thin film. And if they are not too tender, it is best done before they are pasted, as the spirit extracts a yellow dye from many plants, and stains the paper. A few drops of this solution should be mixed with the glue used for pasting. This application not only destroys or keeps off all vermin, but it greatly revives the colors of most plants, giving the collection a more lasting and pleasing air. After several years' experience, no inconvenience has been found from it whatever, nor can any dried plants be long preserved without it.

The herbarium is best kept in a dry room without a constant fire. Linnaeus had a stone building for his museum, remote from his dwelling-house, into which neither fire nor candle was ever admitted, yet nothing was more free from his collection from the injuries of dampness, or other causes of decay. (Smith's Introduction, ch. 24.)
SCIENCE OF GARDENING. Part II.

Sect. VII. Of Methods of Study.

582. There are two methods of acquiring botanical knowledge, analogous to those by which languages are acquired. The first is the natural method, which begins with the great and obvious classes of vegetables, and distinguishes trees, grasses, &c.; next individuals among these; and afterwards their parts or organs. This knowledge is acquired insensibly, as one acquires his mother-tongue. The second is the artificial method, and begins with the parts of plants, as the leaves, roots, &c., ascending to nomenclature and classification, and is acquired by particular study, aided by books or instructors, as one acquires a dead or foreign language. This method is the fittest for such as wish to attain a thorough knowledge of plants, so as to be able to describe them; the other mode is easier, and the best suited for cultivators, whose object does not go beyond that of understanding their descriptions, and studying their physiology, history, and application.

An easy and expeditious mode for gardeners to know plants and study the vegetable kingdom is as follows:

Begin by acquiring the names of a great number of individuals. Supposing the plants growing in a named collection, or that you have any person to tell you their names, then take any old book, and begin at any point (in preference the beginning) of the collection, border, or field, and taking a leaf from the plant whose name you wish to know, put it between the two first leaves of the book, writing the name with a pencil, if you are gathering from a named collection, or if not, merely write a number, and get the name inserted by your instructor afterwards. Gather, say a dozen the first day, carry the book in your pocket, and fix these names in your memory, associated with the form and color of the leaves, by repeatedly turning to them during the moments of leisure of one day. Then, the second day, proceed to the plants, and endeavour to apply the names to the leaves or to the plants, &c. Attach the leaves by two transverse wires, or by any simple process, so as the first set may not fall out when you are collecting a second. Having fixed the first fascicle in your memory, form a second, which you may increase according to your capacity of remembering. Proceed as before during the second day; and the beginning of the third day, begin at your first station, and recall to memory the names acquired during both the first and second day. In this way go on till you have acquired the names of the great majority of the plants in the garden or neighbourhood where you are situated. Nothing is more easily remembered than a word when it is associated with some visible object, such as a leaf or a plant; and the more names of plants we know, the more easy does it become to aid our stock of them. A person who knows only ten plants will require a greater effort of memory to recollect two more, than one who knows a thousand will to remember an additional two hundred. That gardener must have little desire to learn who cannot, in two or three weeks, acquire the names of a thousand plants, if already arranged. If to be collected in the fields, it is not easy getting a thousand leaves or specimens together; but, in general, every gardener requires to charge his memory with the names and ideas or images, of between five hundred and one thousand plants; as being those in general cultivation as agricultural plants, forest-trees, and field-shrubs, horticultural plants or ornamentals, and those requiring eradication as weeds. To acquire the glossology, cut a leaf or other part from the plants indicated in any elementary work on botany which you may possess, as affording examples of each term. You will not be able to get at all the examples; but if you get at one tenth of them, it will prepare you for the next step, which is—To acquire a knowledge of the classes and orders. This is easily done by selecting the blossoms of plants, whose class, &c. is designated in a catalogue. Begin with class I, order I. On looking at any proper catalogue, such as Sweet’s or Donn’s, you will find that there are but few plants in this class, and only one British example which flowers in May. Unless you take that month, therefore, or enjoy the advantages of inspecting hot-house plants, you can do nothing with this class. Proceed to the next order, and so on, examining as many flowers as possible in each class and order, in connection with the descriptions, as given in the elementary guide, in order you may be perfectly familiar with all the classes, and the whole or the greater number of the orders.

Study the descriptions of plants, with the plants before you. For this purpose, procure any good Species Plantarum or Flora, in Latin, if you know a little of that language. See also the Hortus Europaeus, Species Plantarum of the British, as Withering’s Arrangement of British Plants, Murray’s British Flora, or Miller’s Dictionary, in which last are short descriptions both in English and Latin. Persevere in this practice, collecting an hortariam, and writing the complete description of each specimen under it, till all the parts of plants are familiar to you. When that is the case, you will be able, on a plant’s being presented to you which you never saw before, to discover (that is, if it be in flower) first its class and order, and next, by the aid of proper books, its generic and specific names; and this, as far as respects the names of plants, is to attain the object in view.

But to know the name of an object is not to know its nature; therefore having stored up a great many names in your memory, and become familiarised with the plants by which you are surrounded, and with the art of discovering the names of such as may be brought to you, by the Linnean method; the next thing is to study plants according to the natural affinities by which they are grouped to their natural orders, and observing the properties common to each order. Then proceed to study their anatomy, chemistry, and physiology; and lastly, their history and application. For these purposes Smith’s Introduction to Botany, Keith’s Vegetable Physiology, and Millen’s Descriptions of the Species Plantarum of the British, as well as Sowerby’s Exotic and English Botany, or Curtis’s Magazine, are eminently useful for the first department, but they can only come into the hands of a few. Those who understand French will find the elementary works of Decandolle, Richard, and Girardin, of a superior description. The Elements of Decandolle and Sprengel, lately translated, is also a valuable work.

CHAP. IV.

Taxonomy, or the Classification of Plants.

583. Without some arrangement, the mind of man would be unequal to the task of acquiring even an imperfect knowledge of the various objects of nature. Accordingly, in every science, attempts have been made to classify the different objects that it embraces, and these attempts have been founded on various principles. Some have adopted arti-
584. Two kinds of methods have been adopted in arranging vegetables; the natural and the artificial. A natural method is that which, in its distribution, retains all the classes or groups obviously alike; that is, such into which no plants enter that are not connected by numerous relations, or that can be disjoined without doing a manifest violence to nature. An artificial method is that whose classes are not natural, but because they collect together several genera of plants which are not connected by numerous relations, although they agree in the characteristic mark or marks, assigned to that particular class or assemblage to which they belong. An artificial method is easier than the natural, as in the latter it is nature, in the former the writer, who prescribes the rules and orders to be observed in distribution. Hence, likewise, as nature is ever uniform, there can be only one natural method: whereas artificial methods may be multiplied almost ad infinitum, according to the several different relations under which bodies are viewed.

585. The object of both methods is to promote our knowledge of the vegetable kingdom: the natural method, by generalising facts and ideas; and the artificial method, by facilitating the knowledge of plants as individual objects. The merits of the former method consist in the perfection with which plants are grouped together in natural families or orders, and these families grouped among themselves; the merits of the latter consist in the perfection with which plants are arranged according to certain marks by which their names may be discovered. Plants arranged according to the natural method may be compared to words arranged according to their roots or derivations; arranged according to an artificial method, they may be compared to words in a dictionary. Linnaeus has given the most beautiful artificial system that has ever been bestowed by genius on mankind; and Jussieu has, with unrivalled ability, exhibited the natural affinities of the vegetable kingdom. The following Tables exhibit an outline of both methods:—

586. According to the LINNAEAN Method all Vegetables are furnished with Flowers, which are either

Stamina and pointal in the same flower, Male and female organs distinct.
Stamina not united either above or below, Generally of equal length.

| In Number | One, | Two, | Three, | Four, | Five, | Six, | Seven, | Eight, | Nine, | Ten, | Twelve, Many, frequently twenty, attached to the calyx, | Many, generally upwards of twenty, not attached to the calyx, |

Or unequal length, Two long, and two short, Four long, and two short, Stamina united, by the filaments, one body, into two bodies, into many bodies, by the anthers or tops, into a cylinder, Male organs (stamina) attached to, and standing upon the female (pistilum), 

Stamina and pointal in different flowers, on the same plant, on different plants, along with hermaphrodite flowers, or he concealed from view, and cannot be distinctly described.
587. According to the Method of Jussieu all Vegetables are furnished with Seeds, which are either

| Pistils numerous, and stamens opposite: | 1. - - 8. |
| Pistils solitary, or adhering together, placenta central: | 2. - - 12. |
| Pistils free, or more or less adhering together, always inserted in the calyx: Stamens adhering to corolla, which is not attached to the calyx: | 3. - - 16. |
| Calyx and corolla forming only a single envelop: | 4. - - 20. |
| In which the fructification is visible: | 5. Calyciflora, 36. |
| In which the fructification is concealed: | 6. Corolliflora, 16. |

Classified. | Orders.
--- | ---
Thalami form with distinct petals: | Carniflora, Papaveracea, &c.
Dicotyledonae, having the calyx and corolla distinct: | Caryophyllaceae, Linaceae, &c.
Acotyledones: vegetable beings composed of a single tissue unprovided with vessels, and of which the embryo is without cotyledons: | Simaroubae, Ochiaceae.

The names of the classes are of very little consequence in this method, and the number of orders is not to be considered as fixed. That part of a system so new and so comprehensive necessarily admits of much improvement by the progress of the time. The order is too arbitrary, dividing than by uniting. The names of the orders indicate at the same time examples of each, as Ranunculaceae, Ranunculus, &c.

Sect. I. The Hortus Britannicus arranged according to the Linnaean System.

558. The plants grown in Britain, whether native or exotic, are thus arranged according to the Linnaean system. The genera, of which there are species natives of the country, are here marked (*), for the sake of those who may wish to arrange a herbarium or growing collection of indigenous plants according to this method. The authorities followed are, Sweet's Hort. Suburb. Lond. 1818, and Smith's Comp. Flora Brit. 1816.

Class I. Monandria. Stamens 1. Containing only two Orders.

1. Monogynia. Style 1. Containing of the natural order of Jussieu, Canon, the genera Canna, Maranta, Thalia, Phyllura, of the artificial order of Persoon, Alpinia, Helenium, Zingiber, Elettaria, Costus, Kambferia, Amomum, Curcuma, Globba; of James, Philodram; of Guajava, Lepia; of Nymphaea, Boronia; of Chenopodium, Polichlux; *Salicornia; of Naiades, *Hippeastrum. 30 Gen. 62 Sp.

Class II. Bisandria. Stamens 2. Orders 5.

1. Monogynia. This, the most natural and numerous order, comprehends the elegant and fragrant Jasminum, the Jasmine, Lilac, Olive, &c.; also Verbenas, and a few labiate flowers with naked seeds, as Salvia, Rosea, &c., natural allies of the fourth class; but having only two stamens, they are necessarily ranged here in the artificial system. It contains of Jasminum, Nectarium, Jasminium; of Olea; *Ligustrum, Ola, Notolea, Chimonanthus, Linocera, Ornus, Syring; of Dianthus, Catalpa; of Tithonias, Fumaria; of Oenothera, Lamia; *Circaea, of Scopolia, *Veronica, Gratiosa, Schwenka, Callistephus; Acanthus, Escaramus, Jussieu, Eratosthenes; of Leguminosae, *Pimpinella, *Uricaria; of Verbena, Galpin; Glahea, Stachycharpha; of Lobelia, *Lygosum, Astethoman, Calina, Ziziphora, Hedefora, Monarda, Romanisias, *Salvia, Collinsonia; of Dipsacus, Murina; of Rosaceae, Acema. 36 Gen. 576 Sp.

2. Digynia, consists only of Geraniaceae, *Anthemis, a genus which, having but two stamens, is separated from its natural family in the third class. 1 Gen. 2 Sp.

1. Monogynia. Fabriaceae is placed here because most of its species have three stamens. Here also we find the sword-leaved plants, Iris, Gladiolus, *Ixia, &c., also Crocus, and numerous grass-like plants, Schoenus, Cyperus, Scirpus, &c.

2. Digynia. This important order consists of the true Grasses. Their habit is more easily perceived than defined; their value, as furnishing herbage for cattle, and grain for man, is sufficiently obvious. No poisonous plant is found among them, except the Lolium temulentum, said to be intoxicating and pernicious in bread. Their genera are not easily defined. Linnaeus, Jussieu, and most botanists, pay regard to the
number of flowers in each spikelet; but in Arundo this is of no moment. Magnificent and valuable works on this family have been published by the comestible and the non-comestible, by Dr. Hort. The Fl. Græca also is rich in this department, especially the last part of it, where Ficaria is noticed. Much is to be expected from scientific agriculturists; but nature so absolutely, in general, accommodates each grass to its season, that nothing is so constantly to be expected as to overcome their habits, insomuch that few grasses can be generally cultivated. Of the Compositae, the Trichodorus, Scrophularia, Agrimonia, Kniphofia, Potentilla, Tennis, Tritecum, Securidaca, Hylotelephium, Echinops, Caryophyllum, Gynura, Feyritzia, Unica, Zizyphus, Erythrina, Cercis, Orchis, Pennisetum, Meridian, Hopia, Staipa, Pharaonius, Alchorneae, Hevea, Krambe, Hisbome, Heranium of Cephospermum, Chepromedon, Bit, Salvia, Icaena, Acanthophyllum, Euphorbia, Oenothera, Balsamina, Chebula, Festuca, Cynodon, Cephalanthus, Lonicera, Alzina, Lythrum, in general, forms the eleventh or twelfth part of the fourth of the fruitation. -- It contains of Restitieus, Eriocarpaceae, and Portulacaceae, of which the latter is the remark of Linnaeus, who detected the cause of a dreadful disease which affected the roots of Linum, in their eating young leaves of Cicuta virosa, under water. -- It contains of Cyanus, Hydrocharideae, Sparganiaceae, Barnacle, Biurepium, Echinops, Hesperisplanta, Tendylidae, Clarkia, Arctida, Ducaea, Vanca, Ammi, Aminum, comminum, Amaubam, Pericymium, Crambe, Cache, Cyperus, Persicaria, to Dr. Mann, every part of its Stipule, Scelina, Knautia, of Alliaria, Plantago, Rupiae, and Spermacoce. -- incredible. -- It contains of Caryophylles, and of Hopea, to Dr. Hort, its 50 absolute florets. -- It contains of Restitieus, Eriocarpaceae, and Portulacaceae, of which the latter is the remark of Linnaeus, who detected the cause of a dreadful disease which affected the roots of Linum, in their eating young leaves of Cicuta virosa, under water. -- It contains of Cyanus, Hydrocharideae, Sparganiaceae, Barnacle, Biurepium, Echinops, Hesperisplanta, Tendylidae, Clarkia, Arctida, Ducaea, Vanca, Ammi, Aminum, comminum, Amaubam, Pericymium, Crambe, Cache, Cyperus, Persicaria, to Dr. Mann, every part of its Stipule, Scelina, Knautia, of Alliaria, Plantago, Rupiae, and Spermacoce. -- incredible. -- It contains of Caryophylles, and of Hopea, to Dr. Hort, its 50 absolute florets. -- It contains of Restitieus, Eriocarpaceae, and Portulacaceae, of which the latter is the remark of Linnaeus, who detected the cause of a dreadful disease which affected the roots of Linum, in their eating young leaves of Cicuta virosa, under water. -- It contains of Cyanus, Hydrocharideae, Sparganiaceae, Barnacle, Biurepium, Echinops, Hesperisplanta, Tendylidae, Clarkia, Arctida, Ducaea, Vanca, Ammi, Aminum, comminum, Amaubam, Pericymium, Crambe, Cache, Cyperus, Persicaria, to Dr. Mann, every part of its Stipule, Scelina, Knautia, of Alliaria, Plantago, Rupiae, and Spermacoce. -- incredible. -- It contains of Caryophylles, and of Hopea, to Dr. Hort, its 50 absolute florets. -- It contains of Restitieus, Eriocarpaceae, and Portulacaceae, of which the latter is the remark of Linnaeus, who detected the cause of a dreadful disease which affected the roots of Linum, in their eating young leaves of Cicuta virosa, under water. -- It contains of Cyanus, Hydrocharideae, Sparganiaceae, Barnacle, Biurepium, Echinops, Hesperisplanta, Tendylidae, Clarkia, Arctida, Ducaea, Vanca, Ammi, Aminum, comminum, Amaubam, Pericymium, Crambe, Cache, Cyperus, Persicaria, to Dr. Mann, every part of its Stipule, Scelina, Knautia, of Alliaria, Plantago, Rupiae, and Spermacoce. -- incredible. -- It contains of Caryophylles, and of Hopea, to Dr. Hort, its 50 absolute florets. -- It contains of Restitieus, Eriocarpaceae, and Portulacaceae, of which the latter is the remark of Linnaeus, who detected the cause of a dreadful disease which affected the roots of Linum, in their eating young leaves of Cicuta virosa, under water. -- It contains of Cyanus, Hydrocharideae, Sparganiaceae, Barnacle, Biurepium, Echinops, Hesperisplanta, Tendylidae, Clarkia, Arctida, Ducaea, Vanca, Ammi, Aminum, comminum, Amaubam, Pericymium, Crambe, Cache, Cyperus, Persicaria, to Dr. Mann, every part of its Stipule, Scelina, Knautia, of Alliaria, Plantago, Rupiae, and Spermacoce. -- incredible. -- It contains of Caryophylles, and of Hopea, to Dr. Hort, its 50 absolute florets. -- It contains of Restitieus, Eriocarpaceae, and Portulacaceae, of which the latter is the remark of Linnaeus, who detected the cause of a dreadful disease which affected the roots of Linum, in their eating young leaves of Cicuta virosa, under water. -- It contains of Cyanus, Hydrocharideae, Sparganiaceae, Barnacle, Biurepium, Echinops, Hesperisplanta, Tendylidae, Clarkia, Arctida, Ducaea, Vanca, Ammi, Aminum, comminum, Amaubam, Pericymium, Crambe, Cache, Cyperus, Persicaria, to Dr. Mann, every part of its Stipule, Scelina, Knautia, of Alliaria, Plantago, Rupiae, and Spermacoce. -- incredible. -- It contains of Caryophylles, and of Hopea, to Dr. Hort, its 50 absolute florets. -- It contains of Restitieus, Eriocarpaceae, and Portulacaceae, of which the latter is the remark of Linnaeus, who detected the cause of a dreadful disease which affected the roots of Linum, in their eating young leaves of Cicuta virosa, under water. -- It contains of Cyanus, Hydrocharideae, Sparganiaceae, Barnacle, Biurepium, Echinops, Hesperisplanta, Tendylidae, Clarkia, Arctida, Ducaea, Vanca, Ammi, Aminum, comminum, Amaubam, Pericymium, Crambe, Cache, Cyperus, Persicaria, to Dr. Mann, every part of its Stipule, Scelina, Knautia, of Alliaria, Plantago, Rupiae, and Spermacoce. -- incredible. -- It contains of Caryophylles, and of Hopea, to Dr. Hort, its 50 absolute florets. -- It contains of Restitieus, Eriocarpaceae, and Portulacaceae, of which the latter is the remark of Linnaeus, who detected the cause of a dreadful disease which affected the roots of Linum, in their eating young leaves of Cicuta virosa, under water. -- It contains of Cyanus, Hydrocharideae, Sparganiaceae, Barnacle, Biurepium, Echinops, Hesperisplanta, Tendylidae, Clarkia, Arctida, Ducaea, Vanca, Ammi, Aminum, comminum, Amaubam, Pericymium, Crambe, Cache, Cyperus, Persicaria, to Dr. Mann, every part of its Stipule, Scelina, Knautia, of Alliaria, Plantago, Rupiae, and Spermacoce. -- incredible. -- It contains of Caryophylles, and of Hopea, to Dr. Hort, its 50 absolute florets. -- It contains of Restitieus, Eriocarpaceae, and Portulacaceae, of which the latter is the remark of Linnaeus, who detected the cause of a dreadful disease which affected the roots of Linum, in their eating young leaves of Cicuta virosa, under water. -- It contains of Cyanus, Hydrocharideae, Sparganiaceae, Barnacle, Biurepium, Echinops, Hesperisplanta, Tendylidae, Clarkia, Arctida, Ducaea, Vanca, Ammi, Aminum, comminum, Amaubam, Pericymium, Crambe, Cache, Cyperus, Persicaria, to Dr. Mann, every part of its Stipule, Scelina, Knautia, of Alliaria, Plantago, Rupiae, and Spermacoce. -- incredible. -- It contains of Caryophylles, and of Hopea, to Dr. Hort, its 50 absolute florets. -- It contains of Restitieus, Eriocarpaceae, and Portulacaceae, of which the latter is the remark of Linnaeus, who detected the cause of a dreadful disease which affected the roots of Linum, in their eating young leaves of Cicuta virosa, under water. -- It contains of Cyanus, Hydrocharideae, Sparganiaceae, Barnacle, Biurepium, Echinops, Hesperisplanta, Tendylidae, Clarkia, Arctida, Ducaea, Vanca, Ammi, Aminum, comminum, Amaubam, Pericymium, Crambe, Cache, Cyperus, Persicaria, to Dr. Mann, every part of its Stipule, Scelina, Knautia, of Alliaria, Plantago, Rupiae, and Spermacoce. -- incredible. -- It contains of Caryophylles, and of Hopea, to Dr. Hort, its 50 absolute florets. -- It contains of Restitieus, Eriocarpaceae, and Portulacaceae, of which the latter is the remark of Linnaeus, who detected the cause of a dreadful disease which affected the roots of Linum, in their eating young leaves of Cicuta virosa, under water. -- It contains of Cyanus, Hydrocharideae, Sparganiaceae, Barnacle, Biurepium, Echinops, Hesperisplanta, Tendylidae, Clarkia, Arctida, Ducaea, Vanca, Ammi, Aminum, comminum, Amaubam, Pericymium, Crambe, Cache, Cyperus, Persicaria, to Dr. Mann, every part of its Stipule, Scelina, Knautia, of Alliaria, Plantago, Rupiae, and Spermacoce. -- incredible. -- It contains of Caryophylles, and of Hopea, to Dr. Hort, its 50 absolute florets.
Class VIII. Orchidaceae. Stamen 8, Orders 4.

1. Monocots. A rather various and rich order, consisting of the well-known Trigonia, or Nasturtium, whose original Leaves are characteristic of the order, and includes a great many species, including many having curious flowers. —It contains of Geraniaceae; Trigonaceae; and others. Orders 3.

2. Dicots. With only a few small, but known; among them are Gelsemium, Americano, and Mock-orange. The former belongs to Chickweed, and the latter to Cregypogon.

3. Trianthema. With only a few small, but known; among them are Gelsemium, Americano, and Mock-orange. The former belongs to Chickweed, and the latter to Cregypogon.

Class IX. Eucalyptus. Stamen 3, Orders 5.

1. Monocots. A rather various and rich order, consisting of the well-known Trigonia, or Nasturtium, whose original Leaves are characteristic of the order, and includes a great many species, including many having curious flowers. —It contains of Geraniaceae; Trigonaceae; and others. Orders 3.

2. Dicots. With only a few small, but known; among them are Gelsemium, Americano, and Mock-orange. The former belongs to Chickweed, and the latter to Cregypogon.

Class X. Deciduous. Stamen 10, Orders 5.

1. Monocots. A rather various and rich order, consisting of the well-known Trigonia, or Nasturtium, whose original Leaves are characteristic of the order, and includes a great many species, including many having curious flowers. —It contains of Geraniaceae; Trigonaceae; and others. Orders 3.

2. Dicots. With only a few small, but known; among them are Gelsemium, Americano, and Mock-orange. The former belongs to Chickweed, and the latter to Cregypogon.

Class XI. Dicotyledon. Stamen 12 to 19, Orders 6.

1. Monocots. A rather various and rich order, consisting of the well-known Trigonia, or Nasturtium, whose original Leaves are characteristic of the order, and includes a great many species, including many having curious flowers. —It contains of Geraniaceae; Trigonaceae; and others. Orders 3.

2. Dicots. With only a few small, but known; among them are Gelsemium, Americano, and Mock-orange. The former belongs to Chickweed, and the latter to Cregypogon.
2. Angiospermae. Seeds in a capsule, and generally very manynumerous, are the most characteristic of this division. They have a dissoluble ambiguity with some families in Peperidaceae Monogyniae. Some species of Solanum L., such as S. radicans, and Antirrhinum Linnaeus, in which the irregular corolla becomes regular, and the four united are sometimes changed into equal ones; does not do this, as has been asserted, on the action of any extraneous pollen upon the stamens of the parent plant, but is due to the nature of the pollen being abortive.

No method of arrangement, natural or artificial, could accurately be applied to these families. Hence, it is impossible for the interference must be expected in every system. — It contains, for instance, Mantellia, Cymboria, Nemoria, Cylindrocoma, Solanea, Stigma species, Melaleuca, and even to the number of species, to the Polyommata Monogyniae. Its fruit, moreover, is a capsule of one or two carpels, and its two or more separate sections, of which its species are fatal and very poisonous, whereas scarcely any plant has as many members belonging to it as it has. Sir J. E. Smith has good reasons concerning the disease commonly known in America, attributed by Linnaeus to the seeds of Ro- bertya Euphorbiaceae.

The cruciferous plants are vulgarly called mustard, and sometimes of an alkaline nature. The cruciferous plant, which is generally obtainable in very small quantities by di- stillation, is, like the violet, capable of forming in a very high quality. Hence the vast extent of water in which cabbage, and sometimes even the root of this tribe, have been boiled.

It contains Cruciferae, Helophyta, Cardamine, Arabis, Macropondium, Turritis, Barbagoe, *Nasturtium*, *Ebenaceor*, Eriostemon, Euphorbia, Foeniculum, Matthiola, Hisperis, Senecio, and *Caricieae*. It is known that Linnaeus to the seeds of the Robertya Euphorbiaceae.

V. Dicotyledones. Contains of Geraniaceae, Vincetoxicum. 2 Gen. 4 Sp.

X. Dicotyledones. Contains of Geraniaceae, Monocotyledoneae. 1 Gen. 6 S.

XI. Dicotyledones. Contains of Geraniaceae, Monocotyledoneae. 1 Gen. 6 S.

1. Bauhiniae. Contains of Bauhinia, Adansonia, and of the following, without the character of the preceding sec- tions (d) Legumen with scarcely more than one seed; as Pericaria. (b) Silesia downy, without the character of the preceding sec-
3. Polygynia. Trifollets. Florists of the disk in the preceding: perfect or imperfect; those of the margin, of the radulae have the rudiments of pistils in the visible flowers. This order is in: Convolvulaceae.; of Convolvulaceae, than in some of the flowers of the other classes. — It contains of Cucurbitae, an important and useful family of vegetables, and; as Epidendrum, Affaceae., Callianthus, Berckheys, Didelis, Gentes, Ga- nienia, Cryptostemma, Arctocoles, Sphaerozene.; of Cura- diaceae., Diandria.; Monandria.; of Cura- diaceae., Diandria.; Monandria.; of Cypripedium, Polyandria, Melastomodendron, Calapta, Callisten, Arcotes, Otispermum, Othonia, Hippia, Gymnostylis, Ficaria, Ficaria, Menispernum, Parthenium, Pycnonia, Frasera., 120 p.

bodies like eggs are found in them at that period. But these
some flowers are the signs by which the
and destined to produce a brood of maggots, to feed on the
decaying flesh, and to form a dead body for the future, relative to
carps and their inhabiting polyps, led to the

SEC. II. The Hortus inveniens arranged according to the Jussiean System.
589. The plants grown in Britain, whether native or exotic, are thus arranged according to
the system of Jussieu. The genera, of which are species native of the
are marked thus (*) , for the sake of those who may wish to arrange a herbarium or growing
of indigenous plants according to this method. The authorities followed
are, Sweet's Hortus. Sub. Lond. 1816, and Smith's Comp. Flora Brit. 1816.

CLASS I. DIOTIOLEOIDEA. Thalamiflorae, sect. i with nu-
mbers prefixed and numbers oppost to the pets. Five
Orders.

1. Annonaceae, contains of Pent. Polyg. *Myrtaceous,
Ceratocephalus, Zanthorrhiza; of Belland. Triang. Gallarida;
Polyand. Monog. *Actae; of Polyand. Dicog. *Trioena; of

and. Polyg. Dilleniana; *Illicium, Magnolia, *Magnol.;

3. Annonaceae, contains of Polyand. Polyg. Uvaria,
Annona, Pigeon, *Xylopia; of Monogy.

of *Mercur. *Petricia; of Polyg. *Clypeol.;

6. Smilacaceae, contains of Palmeae, *Cardium, *Cardiaca,
Cranea, Myragna, *Eucidium, *Rhipcarpus, *Urania,
Coprosma, *Bucida; Petaria, Cypessus, Isata, Succorcia,

Teudalia, Iberis, *Lapidus, *Cochlearia, *Subulata,
Notastoria, *Sisyrum, *Erysymum, *Notoceras, *Cheir-
Cyanthillium, Raphanus. 49 Gen. 283 Sp.

Crataegus, Dodecan. *Rhus, *Arctostaphylos, *Vaccinium,

14. Myrtaceae, contains of Polyand. *Myrtaceae, Calamula,

15. Apiaceae, contains of Pedand. *Apiaceae, Cephalaria,

17. Umbelliferae, contains of Polyand. *Umbellifer, *Anethum,

18. Apiaceae, contains of Pedand. *Apiaceae, *Stachys,

20. Umbelliferae, contains of Polyand. *Umbellifer, *Helianthus,

21. Apiaceae, contains of Pedand. *Apiaceae, *Stachys,

22. Compositae, contains of Polyand. *Compositae, *Helianthus,

23. Umbelliferae, contains of Polyand. *Umbellifer, *Helianthus,

25. Compositae, contains of Polyand. *Compositae, *Helianthus,

27. Apiaceae, contains of Pedand. *Apiaceae, *Stachys,

28. Compositae, contains of Polyand. *Compositae, *Helianthus,

29. Umbelliferae, contains of Polyand. *Umbellifer, *Helianthus,

30. Apiaceae, contains of Pedand. *Apiaceae, *Stachys,

31. Compositae, contains of Polyand. *Compositae, *Helianthus,

32. Umbelliferae, contains of Polyand. *Umbellifer, *Helianthus,
SCIENCE OF GARDENING. Part II.

Vegetable Organology, or the external Structure of Plants.

590. Vegetables are reducible to classes, according as they are distinguished by a structure, or organisation, more complicated or more simple; or, according as they are found to be formed with or without certain parts or organs entering into the general idea of the plant. The former constitute what may be denominated perfect plants, and form a class comprehending the principal mass of the vegetable kingdom. The latter constitute what may be denominated imperfect plants, and form a class comprehending all such vegetables as are not included in the foregoing class. Such is the arrangement of Keith, from whose work, as by far the best for general purposes, we have chiefly extracted this and the three following chapters.

SUBSEC. 1. Conservative Organs.

591. The conservative organs are such as are absolutely necessary to the growth and preservation of the plant, including the root, trunk, branch, leaf, and frond.

The root is the principal organ of nutrition.

The trunk constitutes the principal bulk of the individual.

The branches are the divisions of the trunk, originating generally in the upper extremity, but often also along the sides.

The leaf is a temporary part of the plant, issuing generally from numerous points towards the extremities of the branches, but sometimes also immediately from the stem or root, and distinguishable by the sight or touch into an upper and under surface, a base and an apex, with a midrib and lateral nerves.

The fruit is to be regarded as a compound of several of the parts already described; it consists of a union or incorporation of the leaf, leaf-stalk, and branch or stem, forming as it were but one organ, of which the constituent parts do not separate spontaneously from one another by means of the fracture of any natural joint, as in the case of plants in general, but adhere together even in their decay.

SUBSEC. 2. Conservative Appendages.

593. The conservative appendages are accessory or supernumerary parts found to accompany the conservative organs occasionally, but not invariably.

Gums, or bubas, are organised substances issuing from the surface of the plant, and containing the rudiments of new and additional parts which they protract; or the rudiments of new individuals which they constitute by detaching, or developing from the parent plant, and fixing themselves in the soil.

Glands are small and minute substances of various different forms, found chiefly on the surface of the leaf and petiole, but often also on the other parts of the plant, and supposed to be organs of secretion.

The tendril is a thread-shaped and generally spiral process issuing from the stem, branch, or petiole, and sometimes even from the expansion of the leaf itself, being an organ by which plants of weak and climbing stems attach themselves to other plants, or other substances for support; for which purpose it seems to be well fitted by nature, the tendril being much stronger than a branch of the same size.

The stipule are small and foliaceous appendages accompanying the real leaves, and assuming the appearance of leaves in miniature.

Ramenta are thin, oblong, and strap-shaped appendages of a brownish color, issuing from the surface of the plant, and somewhat resembling the stipule, but not necessarily accompanying the leaves. The term, which literally signifies bits of chips or shaving, seems to have been given to these appendages; but it may be noted the small and scattered scales that are frequently found on the stems of vegetables, originating in the bark, and giving it a rough or chopped appearance. Hence a branch or stem that is covered with thin and dry scales or flakes is said to be ramentaceous, as in the case of tamarix gallica.

The armature consists of such accessory and auxiliary parts as seem to have been intended by nature to defend the plant against the attacks of animals.

The pubescence is a general term, including under it all sorts of vegetable down or hairiness, with which the surface of the plant may be covered, finer or less formidable than the armature.

Anomalous. There are several other appendages proper to conservative organs, which are so totally different from all the foregoing, that they cannot be classed with any of them; and so very circumstanced in their occurrence, that they do not yet seem to have been designated by any peculiar appellation. The
first anomaly, as affects the conservative appendages, occurs in Dionaea muscipula, or Venus's fly-trap (Fig. 43 a). A second is that which occurs in Sarce- nia purpurea, or purple side-saddle-flower (b). A third, which is still more singular, occurs in ne- penthes distillatoria (c). The last anomaly is that of a small globular and membranaceous bag, at- tached as an appendage to the roots and leaves of some of the aquatics. It is confined only to a few genera, but is to be seen in great abundance on the roots or leaves of the sev- eral species of utricularia inhabiting the ponds and ditches of this country; and on the leaves of aldrovanda vesiculosa, an inhabitant of the marshes of Italy. In utricularia vulgaris this appendage is pear-shaped, compressed, with an open border at the small end furnished with several slender filaments originating in the margin, and containing a transparent and watery fluid, and a small bubble of air, by means of which it seems to acquire a buoyancy that suspends it in the water.

Subsect. 3. Reproductive Organs.

594. The reproductive organs are such parts of the plant as are essential to its propag- ation, corresponding in extent to the fructification of Linnaeus, which he has elegantly defined to be a temporary part of the vegetable, whose object is the reproduction of the species, terminating the old individual, and beginning the new. It includes the flower with its immediate accompaniments or peculiarities, the flower-stalk, receptacle, and inflorascence, together with the ovary or fruit.

The flower, like the leaf, is a temporary part of the plant, issuing generally from the extremity of the branches, but sometimes also from the root, stem, and even leaf, being the apparatus destined by nature for the production of the fruit, and being also distinguishable, for the most part, by the brilliance of its coloring or the sweetness of its smell. It has been happily styled by Pliny, the joy of plants, "Ros gaudium arborum"; of which the lily, the tulip, and the rose are the most beautiful.

The flower-stalk is a particular mode of aggregation in which the different parts of the flower, or between the flower and the plant, whether immediate and sessile, or mediate and supported upon a flower-stalk. Some botanists have considered it as a part of the flower itself, though this view of the sub- ject is not entirely correct; but it is at any rate a part of the fructification, and cannot possibly be wanting in the case of any flower whatever. Like the flower-stalk, it has been discriminated by botanists into two different species, which are not indeed designated by proper names, but characterised by the appellations of the proper receptacle, and the common receptacle.

The inflorascence is the peculiar mode of aggregation in which flowers are arranged or distributed upon the plant, whenever it is called sometimes also the mode of flowering.

The fruit. In the progress of fructification, when the several organs of the flower have discharged their respective functions, the petals, the stamens, the style, and often the calyx, wither and fall. The ovary and the appendages are expanded to the plant, and swells and expands till its ripeness reaches maturity. It is now denominated the fruit. But at the period of its complete development it also detaches itself from the plant and drops into the bosom of the earth, containing and protecting the embryo of the future vegetable. The fruit then is the ripened ovary and the parts which it contains. In popular language the term is confined chiefly to such fruits as are esculent, as the apple, the peach, and the cherry, or perhaps to the esculent part only; but with the botanist the matured ovary of every flower, with the parts contained, constitutes the fruit.

Subsect. 4. Reproductive Appendages.

595. Various additional and supernumerary parts, not at all essential to their constitution, because not always present, are often found attending the reproductive organs. Many of them are precisely of the same character with that of the conservative appendages, except that they are of a finer and more delicate texture. Such are the glands, down, pubescence, hairs, thorns, or prickles, with one or other of which the parts of the fructification are occasionally furnished. But others are altogether peculiar to the re- productive organs, and are to be regarded as constituting, in the strict acception of the term, true reproductive appendages. Some of them are found to be proper to the flower, and others to the fruit.

The appendages proper to the flower are the involucre, spathe, and bracte, generally designated by the appellation of floral leaves, as being leaf-like substances situated near the flower, though different in their color, form, or substance, from the real leaves of the plant; together with the nectary, and several other minute appendages supposed to be necessary, though not certainly known to be so.

Appendages of the fruit. When the flower with its appendages has fallen, the ovary, which is still immature, is left attached to the plant, to complete the object of the fructification in the ripening of the contained seed. If it is left without any extraneous or supernumerary appendages, which is a case that often occurs, as in the cherry, apricot, and currant, the fruit is said to be naked. The naked fruit, how- ever, is not to be confounded with the naked seed, from which it is altogether distinct. For it is the want of a conspicuous pericarp that constitutes the naked seed; but it is the want of an additional integument enveloping the pericarp, that constitutes the naked fruit. But all parts of the flower are not always decid-
duous, and it often happens that one or other of them still continues to accompany the pericarp or seed both in its ripening and ripened state, constituting its appendage, and covering it either wholly or in part, or adhering to it in one shape or other.

**Sect. II. Imperfect Plants.**

596. *Plants apparently defective* in one or other of the more conspicuous parts or organs, whether conservative or reproductive, are denominated imperfect. Linnaeus characterised them by the appellation of cryptogamous plants, because their organs of fructification are not yet detected, or are so very minute as to require the aid of the microscope to render them visible; and in the system of Jussieu they are included in the monocotyledoneae and acotyledoneae, composing the cryptogameae of the former, and the whole of the latter division. As in the perfect plants, so in the imperfect plants, the eye readily recognises traces of a similitude or dissimilitude of external habit and deportment characterising the different individuals of which they consist, and suggesting also the idea of distinct tribes or families. And upon this principle different botanists have instituted different divisions, more or less extensive, according to their own peculiar views of the subject. But one of the most generally adopted divisions of imperfect plants is that by which they are distributed into the natural orders of filices, equisitaceae, lycopodinace, musci, hepaticae, algae, licheneae, and fungi. Dillenius, Micheli, Bulliard, Hedwig, and Acharius, have rendered themselves illustrious by the study of these tribes.

**Subsect. 1. Filices, Equisitaceae, and Lycopodinaceae.**

597. The filices, equisitaceae, and lycopodinaceae, are for the most part herbaceous, and die down to the ground in the winter, but they are furnished with a perennial root, from which there annually issues a frond bearing the fructification. The favorite habitations of many of them are heaths and uncultivated grounds, where they are found intermixed with furze and brambles; but the habitations of such as are the most luxuriant in their growth, are moist and fertile spots, in shady and retired situations, as on mossy dripping rocks, or by fountains and rills of water. Some of them will thrive even on the dry and barren rock, or in the chinks and fissures of walls; and others only in wet and marshy situations where they are half immersed in water.

**Subsect. 2. Musci.**

598. The mosses are a tribe of imperfect plants of a small and diminutive size, consisting often merely of a root, surmounted with a tuft of minute leaves, from the centre of which the fructification springs, but furnished for the most part with a stem and branches, on which the leaves are closely imbricated, and the fructification terminal or lateral. They are perennials and herbaceous, approaching to shrubby; or annuals, though rarely so, and wholly herbaceous, the perennials being also evergreens. Their most favorite habitations are bleak and barren soils, such as mountains, heaths, woods, where they are found, not only rooted in the earth, but attached also to the roots and trunks of trees, and even to the flinty rock; or immersed in bogs and ditches, or floating, though fixed by the roots, in streams of running water. As they affect the most barren soils, so they thrive best also in the coldest and wettest seasons. In the drought of summer they wither and languish; but in the more moderate temperature of autumn they begin to recruit, so that even the chilling cold of winter that deprives other plants of their verdure and foliage, and threatens destruction to the greater part of vegetables, tends but to refresh and revive the family of the mosses. (fig. 44.) Hence their capacity of retaining moisture for a great length of time without discovering any tendency to putrefaction, and of recovering their verdure when moistened with water, even after having been completely dried, and kept in a dried state for many years. From the extreme minuteness of their parts, they are apt to be overlooked by the superficial observer, or disregarded by the novice in
botany, who is attracted perhaps only by what is specious in the plant or flower, but who, when the desire of botanical knowledge shall have inspired him with a relish for microscopic observation, will find the study of the mosses to be no less interesting than that of the more perfect plants, and the form and texture of their parts to be no less beautiful and elegant than that of the most gaudy flowers. (Fig. 44.)

Subsect. 3. Hepaticae.

599. The hepaticae are a tribe of small and herbaceous plants resembling the mosses, but chiefly constituting fronds, and producing their fruit in a capsule that splits into longitudinal valves. The name is derived from a Greek word signifying the liver, because perhaps some of them were formerly employed as a remedy in diseases of the liver; or because some of them exhibit, in their general aspect, a slight resemblance to the lobes of the liver. In their habitations, they affect for the most part the same sort of situations as the mosses, being found chiefly in wet and shady spots, by the sides of springs and ditches, or on the shelving banks of rivulets, or on the trunks of trees. Like the mosses, they thrive best also in cold and damp weather, and recover their verdure, though dried, if moistened again with water. The hepaticae and the mosses are indeed so nearly allied, that they have generally been regarded as constituting but one family, and classed together accordingly; the latter under the title of musci frondosi, and the former under that of musci hepatici. Such was the division even of Hedwig; but later botanists have found it to be more consonant to the principles of sound and scientific arrangement, to separate the hepaticae from the mosses altogether, and to convert them into a distinct tribe.

Subsect. 4. Algae and Lichenes.

600. The term algae, or sea-weeds, among modern botanists, includes not merely marine and many other immersed plants, but also a great variety of plants that are not even aquatics. All the algae, or, according to the Jussieuan terminology, algea, however, agree in the common character of having their herbage frondose, or but rarely admitting of the distinction of root, stem, and leaf, and their fructification imbedded either in the substance of the frond itself, or in some peculiar and generally sessile receptacle. The algae were formerly divided into the six following genera, lichen, tremella, fucus, ulva, conferva, byssus; but now the genus lichen forms an order of itself.

601. The utility of the algae is obviously very considerable, whether we regard them as furnishing an article of animal food, or as applicable to medicine and the arts. The fucus edulis, and several other fuci, are eaten and much relished by many people, whether raw or dried, and it is likely that some of them are fed upon by various species of fish. The fucus lichenoides (Turner, c. 118.) is now believed to be the chief material of the edible nests of the East India swallows, which are so much esteemed for soups, that they sell in China for their weight in gold. When disengaged from their place of growth and thrown upon the sea-shore, the European algae are often collected by the farmer and used as manure. They are often also employed in the preparation of dyes, as well as in the lucrative manufacture of kelp, a commodity of the most indispensable utility in the important arts of making soap and glass.

602. The utility of the lichenes is also worthy of notice. The lichen rangiferinus (Fig. 45.) forms the principal nourishment of the rein-deer during the cold months of winter, when all other herbage fails. The lichen islandicus is eaten by the Icelanders instead of bread, or used in the preparation of broths, and like the lichen pulmonarius, has been lately found to be beneficial in consumptive affections. Many of them are also employed in the preparation of some of our finest dyes, or pigments; and it is from the lichen parellus that the chemical analyst obtains his litmus. The lichenes and the mosses seem instituted by nature to provide for the universal diffusion of vegetable life over the whole surface of the terrestrial globe. The powdery and tuberculous lichenes attach themselves even to the bare and solid rock. Having reached the maturity of their species, they die and are converted into a fine earth, which forms a soil for the leathery lichenes. These again decay and moulder into dust in their turn; and the depth of soil, which is thus augmented, is now capable of nourishing and supporting other tribes of vegetables. The seeds of the mosses lodge in it, and spring up into
plants, augmenting also by their decay the quantity of soil, and preparing it for the support of plants of a more luxuriant growth, so that in the revolution of ages even the surface of the barren rock is covered with a soil capable of supporting the loftiest trees.

**Subsect. 5. Fungi.**

603. *The fungi are a tribe of plants whose herbage is a frond of a fleshy or pulpy texture, quick in its growth, and fugacious in its duration, and bearing seeds or gems in an appropriate and exposed membrane, or containing them interspersed throughout its mass.* But this rule is not without its exceptions; for many of the fungi are converted, during the process of vegetation, or rather when their vegetation is over, into a tough, leathery, and even woody substance, which gives them a permanency beyond that of their congeneres, and a trait of character that is not included in the above definition. They are also a tribe of plants that may be regarded as the lowest in the vegetable scale, exhibiting a considerable resemblance to the tribe of zoophites, and thus forming the connecting link between the vegetable and animal kingdoms. The habitations they affect are very various, many of them vegetating only on the surface of the earth (fig. 46, a), and some of them even buried under it; others on stumps and trunks of rotten trees (b); others on decayed fruit; others on damp and wet walls; and others on animal ordure.

**Conservative organs.** Many of the fungi are altogether destitute of any conspicuous root, being attached to some appropriate basis of support merely by means of a large and flattened surface. The frond is often merely a thin, flat, and leathery sort of substance, adhering to a basis of support by means of the whole of its under-surface, as in the boleti. In others it is globular and sitting, as in lycoperdon; and in others, it is bell-shaped and sitting, as in nudularia.

**Reproductive organs.** In fungi furnished with gills and a curtain, if the inner surface of the curtain is carefully examined with a good magnifier, before the time of its natural detachment from the stipe or pileus, there will be found adhering to it a number of fine and delicate threads supporting small globules; and in such as have no curtain the same sort of substances may be found adhering to the edge of the pileus. These Hedwig regards as stamens. If the gills are next examined in the same manner and about the same time, there will be found sitting on their edge or surface a multitude of small, tender, and cylin- drical substances, some of which are surmounted with a small globule, and others not. These he regards as being probably the styles and stamens. Similar substances may be detected on the other genera of fungi also. But from the extreme minuteness of their parts, and from their strong similitude to the down with which the finer organs of vegetables are generally covered, it is easy to perceive how very difficult it must be to decide upon their true character.

604. **Uses of the fungi.** The powder of the lycoperdons is said to be an excellent styptic; and is remarkable also for its property of strongly repelling moisture. If a basin is filled with water, and a little of the powder strewed upon the surface so as to cover it thinly, the hand may be plunged into it and thrust down to the bottom without being wetted with a single drop of water. Several of the boleti, when dried, afford a very useful tinder; and several of the agarics and tubers are used as articles of food, or as ingredients in the preparation of seasoning. The truffle is much esteemed for the rich and delicate flavor which it imparts to soups and sauces; and the mushroom for its esculent property, and utility in the preparation of ketchup.

---

**Chap. VI.**

**Vegetable Anatomy, or the internal Structure of Plants.**

605. *The organs of plants discoverable by external examination, are themselves reducible to component organs, which are again resolvable into constituent and primary organs. These are called the decomposite, the composite, and the elementary.*

**Sect. I. Decomposite Organs.**

606. *The decomposite organs constitute the vegetable individual, and are distinguishable by external examination; to the dissection of which we will now proceed, taking them in the retrograde order of the seed, pericarp, flower, leaf, gem, and caudex, or branch, stem, and root, with their decomposite appendages.*

607. *The seed. The mass of the seed consists of two principal parts, distinguishable without much difficulty; namely, the integuments and nucleus, or embryo and its envelopes. The integuments proper to the seed*
are two in number, an external integument and an internal integument; which are sometimes, however, enveloped by an additional integument constituting an appendage of the seed, under the title of the pericarp, involucrem, or calyx. The external integument (or coat) is usually detachable in the early stages of its growth, but detachable at the period of the maturity of the fruit, when it is generally of a membranous or leathery texture; though sometimes soft and fleshy, and sometimes both, according as the fleshy capsule or the testa, is easily distinguishable in the case of an herbaceous plant or of some of the fruits of the dicotyledonous plants. The testa forms the interior integument. Like the testa, to which indeed it adheres, it may be easily distinguished in the garden-bean (fig. 47.), or in a rye-walnut; in which last it is a fine transparent and net-like membrane.

608. The nucleus is that part of the seed which is contained within the proper integuments, consisting of the albumen with the villae, when present, and enclosing the embryo. The embryo is an organ resembling in its consistence the white of an egg, and forming, in most cases, the exterior portion of the nucleus, but always separating from the interior or remaining portion. The villae is an organ of a fleshy but firm consistence, situated, when present, between the albumen and embryo; to the form of which it is attached only by adhesion, but to the latter by incorporation of substance, so as to be inseparable from it, except by force. The embryo (fig. 47. a) is the last and most essential part of the seed and final object of the fruiting action, as being the germ of the future plant, is a small and often very minute organ, enclosed within the albumen and occupying the centre of the seed. The cotyledon or seed-lobes (b), is that portion of the embryo which is best distinguished, and springs up during the process of germination into what is usually denominated the seminal leaf, if the lobe is solitary; or seminal leaves, if there are more lobes than one. In the former case the seed is said to be monocotyledous; in the latter case, it is said to be dicotyledous. Dicotyledonous seeds, which constitute the majority of the seeds of the dicotyledons, are so called because the cotyledon consists of one lobe only, falling short of the general number, so there are also a few whose cotyledon is divisible into several lobes, exceeding the general number. They have been denominated polycotyledonous seeds, and are exemplified in the case of Lepidium sativum or common garden-cress, in which the lobes are six in number; as in that also of the different species of the genus Pinus, in which they vary from three to twelve. But although by far the greater number of seeds are furnished with two cotyledons, or with a cotyledon divisible or not divisible into several lobes, there is also a considerable proportion in which the cotyledon is altogether wanting, or at least being regarded by botanists in general, as according to Gartner, are exemplified in the fucis, ferns, and fungi, the embryo being merely a germinating ciliate imbedded in the surface of a vitellus which forms the mass of the seed. But Hedwig, to whose opinions on this subject adherence is as we shall see, by many botanists, is of opinion that the seeds of the plants in question are furnished with cotyledons as well as of those other plants, and that no seed whatever is without them. This is a case, however, in which the general opinion of botanists is against him, as may be seen from the many systems founded upon the presence, or absence, or number of the cotyledons, and exemplified, as we have seen, in that of the great and justly celebrated Jussieu, whose primary divisions are those of acr��otyledonous, monocotyledonous, and dicotyledonous plants, the polycotyledonous being thought to be too few in number to constitute a separate division. It should be recollected, however, that the above divisions were instituted at a time when the subject had not yet undergone any thing like a rigorous scrutiny, that already many changes have been found necessary, and that future investigations will in all probability point out the necessity of more. In watching the germination of fern-seed, Mirbel observed some substances which he regards as cotyledons, and so far supports the position of Hedwig. The plantulae, or future plant, is the interior portion of the embryo, and seed of vegetative life. In some seeds it is so minute as to be scarcely perceptible; while in others it is so large as to be divisible into distinct parts, as in the garden-bean.

609. The epicarp, which is in different species of fruit assumes so many varieties of consistence, acquires its substance by seeds, not so much from a diversity of consistence as of modification. The valves of the capsule, but particularly the partitions by which it is divided into cells, are composed of a thin and leathery membrane, or of an epidermis covering a pulp more or less inured, and interspersed with longitudinal fibres. The exocarp, the outer and next above, is composed of epidermis and of the compound of an epidermis, or an envelope, which is sometimes so interwoven with a multiplicity of longitudinal fibres as to seem to consist wholly of threads, as in the cocoa-nut. The berry is composed of a very fine epidermis enclosing a soft and juicy pulp. The scales of the stroble are composed of a tough and leathery epidermis, enclosing a spongious and often highly inured pulp interspersed with compound fibres that pervade also the pips. The pips or seeds are surrounded by a mesocarp, consisting of the fleshy pulp, which is sometimes so interwoven with a multiplicity of longitudinal fibres as to seem to consist wholly of threads, as in the cocoa-nut. The berry is composed of a very fine epidermis enclosing a soft and juicy pulp. The scales of the stroble are composed of a tough and leathery epidermis, enclosing a spongious and often highly inured pulp interspersed with compound fibres that pervade also the pips. The pips or seeds are surrounded by a mesocarp, consisting of the fleshy pulp, which is sometimes so interwoven with a multiplicity of longitudinal fibres as to seem to consist wholly of threads, as in the coco
Buds are composed externally of a number of spoon-shaped scales, closely converging towards a point in the apex, and often cemented together by means of a glutinous adherent cement. The margin of each scale is often indurated, and the whole shows the lines of growth. If cut transversely, or longitudinally, the cells of the epidermis enclose a pulpy interspersed with a network of fibres, but unaccompanied with longitudinal threads. If cut longitudinally, the scales of a leaf-bud are taken and stripped off, and the remaining part carefully opened up, it will be found to consist of the rudiments of a young branch terminated by a bunch of incident leaves imbedded in a white and cottony down, being minute but complete in all their parts and proportions, and folded or tied up in the bud in a peculiar and determinate manner.

613. The term caudex, in its present application, is to be understood as including the whole mass or body of a plant, as distinct from the temporary parts of the plant, or parts already investigated; and as comprehending both the caudex ascends, and caudex descends of Linnaeus, or the trunk and its divisions, with the root and its divisions. In opening up and dissecting the caudex, whether ascending or descending, the dissector will soon discover that its internal structure, like its external aspect or habit, is not materially different in different tribes of plants.

614. The first general mode of the internal structure of the caudex is that in which an epidermis encloses merely a homogeneous mass of pulp or slender fibre, which forms the principal body of the caudex, and becomes somewhat indurated with age, though not woody, without discovering any further variety of component parts. This, Mirbel observes, is the simplest mode of internal structure existing among vegetables; it is exemplified in the lower orders of softwoods and imperfect plants, particularly the algea and fungi.

615. The second general mode of internal structure of the caudex is that in which an epidermis encloses two or more substances, or assemblages of substances, totally heterogeneous in their character. A very strong and certain sign of this is the fact that in which an epidermis or the integument is found to enclose a soft and pulpy mass, interspersed with a number of longitudinal nerves or fibres, or bundles of fibres, extending from the base to the apex, and disposed in a peculiar mode characteristic of a tribe or genus. This mode is exemplified in trees and shrubs, which have vessels chiefly in herbarious and annual or biennial plants. (fig. 48.)

The pulp being solid, as in epidium filix-mas, and tubular, as in the garden parsnip or common hemlock. A second variety of this mode is that in which a strong and ovoid-thick bark encloses a circular layer of longitudinal fibres, or several such circular and concentric layers, interwoven with thin transverse and divergent layers of pulp, so as to form a firm and compact cylinder, in the centre of which is lodged a pulp or pith. This mode is best exemplified in trees and shrubs. (fig. 49.)

The wood being imperfect in the root of the beet, the common bramble, and burdock; and perfect in the oak or alder.

616. The appendages of the plant, whether conservative or reproductive, exhibit nothing in their internal structure that is at all essentially different from that of the organs that have been already described.

Sect. II. Composite Organs.

617. From the preceding analysis, it appears the composite organs are reducible to one or other of the several following substances, namely, epidermis, pulp, pith, cortical layers, ligneous layers, and vegetable fibre. These now remain to be further analysed, under the title of composite organs, as being still compound, with a view to reach the ultimate and elementary organs of the vegetable subject.

618. Structure of the vegetable epidermis. The epidermis of the vegetable, which, from its resemblance to that of the animal, has been designated by the same name, is the external envelope or integument of the plant, extending over the whole surface, and covering the root, stem, branches, leaves, flower, and fruit, with their appendages; the summit of the plant only excepted. But although it is extended over the whole surface of the plant, it is not of equal consistence throughout. In the root and trunk it is a tough and leathery membrane, or it is a crust of considerable thickness, forming a notable portion of the bark, and assuming some peculiar shade of color, while in the leaves, flowers, and tender shoots, it is a fine and delicate membrane, and when adherent, it is always tinged with some peculiar shade, which it borrows from the parts immediately beneath it. Du Hamel, Saussure, Hedwig, Comparreti, Bauer, and others, have examined the epidermis, and, according to their descriptions, it resembles that of leafy trees, layers, which are many and set in a series, being very easily distinguished, particularly in that of the paper-bark, the bark of which may, perhaps, be regarded as a succession of individual cuticles.

619. The pulp is a soft and juicy substance, constituting the principal mass of succulent plants, and a notable part of the tissues, even of woody plants. It constitutes the principal mass of many of the fungi and lichens, and of herbaceous plants in general. Of those phytologists who have described the pulp, Mirbel is considered the most accurate. He compares it to clusters of small and hexagonal cells or bladders, containing for the most part a colorless and apparent starch or the form of a spheroid and a delicate membrane, in which no traces of organisation are to be distinguished. In the trunk of what are called dicotyledonous plants, he regards the pulp, or cellular tissue, as consisting of two distinct portions, which he designates by the respective appellations of the herbaceous tissue, and the parenchyma. The former is the exterior portion of the cellular tissue, of which it always contains a resinosous and colored juice, that communicates its peculiar tinge to the epidermis. The latter is the interior portion of the tissue, composed also of cells, but differing from those of the herbaceous tissue in containing only a watery juice without color, because it has been exposed to the action of the light, though in the cactus and many of the craterary plants, the watery juice is said to be also often colored. But in the description of the vegetable pulp, the only distinction necessary to be made is that by which it is divided into two parts, namely, an apparatus of hexagonal cells or vesicles, and a contained juice, whether colorless or colored, the union of which substances forms a true pulp.
Book I.

INTERNAL STRUCTURE OF PLANTS.

620. The pith, as has been already shown, is a soft and spongy, but often succulent substance, occupying the centre of the root, stem, and branches, and extending in the direction of their longitudinal axis, in which it is enclosed as in a tube. The substance constituting it is precisely similar to that of the pulp of a well-composed assemblage of hexagonal cells containing a watery and colorless juice, or of cellular tissue and a parenchyma.

621. The cortical layers, or interior and concentric layers, constituting the mass of the bark, are situated immediately under the cellular interstice, where that interstice exists, and where, not immediately under the epidermis; or they are themselves external. They are distinguishable chiefly in the bark of woody plants, but not, however, in the lime-tree. They are composed of two elements or parts — bundles of longitudinal fibres constituting a network (fig. 50.), and a mass of pulp more or less imbedded, filling up the meshes. The innermost of the layers, a single layer, is the pith, and was used by the ancients for writing on before the invention of paper. It is the finest and most delicate of them all, and often most beautifully reticulated (fig. 51. a), and varied by bundles of longitudinal fibre (b). But the liber of daphne isretato is remarkable for its beautiful and delicacy of texture in the network of pulp, which is not inferior to that of the finest lace, and at the same time so very soft and flexible that in countries of which the tree is a native the lace of the liber is often made to supply the place of a neckcloth. If the cortical layers are injured or destroyed by accident, the part destroyed is again regenerated, and the wound healed up without a scar. But if the wound penetrates beyond the liber, the part destroyed is no longer regenerated. Or if a tree is bent so as to break part of the cortical fibres, and then propped up in its former position, the fractured fibres will again unite. Or if a portion of the stem is entirely decorticated and covered with a piece of bark, even from another tree, the two different barks will unite. Hence the difficulty in ascertaining how far the liber extends. Another interesting point is the origin of grafting, which is always effected by a union of the liber of the grafted and stock.

622. The ligneous layers, or layers constituting the wood, occupy the intermediate portion of the stem between the bark and pith; and are distinguishable into two different sorts — concentric layers and divergent layers. (fig. 50.)

623. The concentric layers, which constitute by far the greater part of the mass of the wood, are sufficiently conspicuous for the purpose of exemplification on the surface of a horizontal section of most trunks or branches, as on that of the oak and elm. But though they are generally described as being concentric, they are not always strictly so. For they are often found to extend more on the one side of the axis of the stem or branch, than on the other. Some authors say the excess is on the north side, but others say it is on the south side. The former account for it by telling us it is because the north side is sheltered from the sun; and the latter by telling us it is because the south side is sheltered from the cold; although it cannot always be the case, for in some of our trees, which have been also thought to be sufficiently striking and uniform to serve as a sort of compass, by which the bewildered traveller might safely steer his course, even in the recesses of the most extensive forest. But Du Hamel has shown that the sun has sometimes on one side of the stem, and sometimes on the other, according to the accidental situation of the great roots and branches; a thick root or branch producing a proportionately thick layer of wood on the side of the stem from which it issues. The layers are indeed sometimes more in number on the one side than on the other, as well as thicker. But this is the exception, and not the rule. They are thickest, however, on the side on which they are fewest, though not of the same thickness throughout. Du Hamel, after counting twenty layers on the one side of the transverse section of the trunk of an oak, found only fourteen on the other. But the fourteen exceeded the twenty in thickness by one fourth part. But the layers thus discoverable on the horizontal section of the trunk are not all of an equal consistency throughout, there being an evident diminution in their degree of solidity from the centre, where they are hardest, to the circumference, where they are softest. The outermost layer, which is the softest of all, is denominated the alburnum, and is usually white or yellow in colour. In the later layers, either of wood or bark, from which character, as well as from its softer texture, it is also easily distinguished, though in the case of some plants, as in that of the poplar and lime-tree, this peculiarity of character is not very apparent. From the peculiarity of external character, however, it which it possesses in general, it was at one time supposed that from that which was its original, a sort of general character, of its own peculiarities, whose physiological opinions were often whimsical, supposed it to be something analogous to the fat of animals, and intended perhaps to serve as a sort of nutriment to the plant in winter. But it is now known to be merely wood in a less condensed state, being yet lighter and softer than the interior layers, and yet acquiring strength and solidity with age. It does not, however, acquire its utmost degree of solidity till after a number of years, as is plain from the regular gradation observable in the solidity of the different layers. But if a tree is felled a year before it is cut down, then the alburnum is converted into wood in the course of that year.

624. The divergent layers which intersect the concentric layers in a transverse direction, constitute also a considerable proportion of the wood, as may be seen in a horizontal section of the fir or birch, or of almost any woody plant, on the surface of which they present an appearance like that of the radii of a circle.

625. The structure of the concentric layers will be found to consist of several smaller and component layers, which are themselves composed of layers smaller still, till at last they are incapable of farther division. The concentric layers are composed of longitudinal fibres, generally forming a network, and the divergent layers, of parallel threads or fibres of cellular tissue, extending in a transverse direction, and filling up the interstices of the net; the two sets of fibres being interwoven and interlaced together to form an integral body in the wooden layers; and thus corresponding exactly to the description given of them by Grew and Malpighi, in which the longitudinal fibres are compared to the warp, and the transverse fibres to the woof of a web.

626. The structure of the stem in plants that are purely herbaceous, and in the herbaceous parts of woody plants, is very similar to that of the composite and other tolerable and ornamental plants, presenting to the eye throughout its whole extent, as in the stipe of aspidium filix-mas, or leaf-stalk of the elder. These fibres, when viewed superficially, appear to be merely individuals, but when inspected minutely, and under the microscope, are found to be provided with tracheides and other peculiar fibres, and to be formed into a number of component fibres, till at last you can divide them no longer. If the fibres of the bark are separated by the destruction of a part, the part is again regenerated, and the fibres are again united, without any apparent alteration. But if the fibres of the woody part are separated by the destruction of a part, the part is never regenerated, and the fibres are never united.
From the previous analysis of the composite organs it appears they are all ultimately reducible to fibres, cellular tissue with or without parenchyma, and reticulated membrane, which we must consequently regard as being, under one modification or other, the ultimate and elementary organs of which the whole mass of the plant is composed. If it is asked of what the elementary organs are themselves composed, the reply is, they are composed, as appears from the same analysis, of a fine, colorless, and transparent membrane, in which the eye, aided by the assistance even of the best glasses, can discover no traces whatever of organisation; which membrane we must also regard as constituting the ultimate and fundamental fabric of the elementary organs themselves, and by consequence of the whole of the vegetable body. It has been asked by some phytologists whether or not plants are furnished with vessels analogous to the blood-vessels of the animal system. But if it is admitted that plants contain fluids in motion, which cannot possibly be denied, it will follow, as an unavoidable consequence, that they are furnished with vessels conducting or containing such fluids. If the stem of a plant of marigold is divided by means of a transverse section, the divided extremities of the longitudinal fibres, arranged in a circular row immediately within the bark, will be distinctly perceived, and their tubular structure demonstrated by means of the orifices which they present, particularly when the stem has begun to wither. The same sort of structure may be observed in the stem of eucurisitaceous plants also, particularly in that of the gourd, in which there are besides discoverable several sets of longitudinal tubes situated near the centre, and of considerable diameter. Regarding it, therefore, as certain that plants are furnished with longitudinal tubes, as well as with cells or utricles for the purpose of conveying or containing their alimentary juices, we proceed to the specific illustration of both, together with their peculiarities and appendages.

628. The utricles are the fine and membranous vessels constituting the cellular tissue of the pith and pulp already described, whether of the plant, flower, or fruit. Individually they resemble oblong bladders inflated in the middle, as in the case of some plants; or circular or hexagonal cells, as in the case of others. Collectively they have been compared to an assemblage of threads of contiguous bladders or vesicles, or to the bubbles that are found on the surface of liquor in a state of fermentation. Simple tubes (fig. 52.) are the largest of all the large tubes, and are formed of a thin and entire membrane, without any perceptible disruption of it; and are found chiefly in the bark, though not confined to it, as they are to be met with also in the underneath and matured wood, as well as in the fibre of herbaceous plants. Furcal tubes resemble the simple tubes in their general aspect; but differ from them in being pierced with small holes or pores, which are often distributed in regular and parallel rows. They are found in most abundance in woody plants, and particularly in wood that is firm and compact, like that of the oak; but they do not, like the simple tubes, seem destined to contain any oily or resiny juice. Spiral tubes are fine, transparent, and thread-like substances, occasionally interpersed with the other tubes of the plant, but distinguished from them by their formed from right to left, or from left to right, in the form of a corkscrew. They occur in most abundance in herbaceous plants, particularly in aquatics. False spiral tubes are tubes apparently spiral on a slight inspection, but which, upon minute examination, are found to derive their appearance mostly from their being cut transversely by parallel fissures. Mixed tubes are tubes combining in one individual twen more of the foregoing varieties. Mirbel exemplifies them in the case of the umbellatus, in which the porous tubes, spiral tubes, and false spiral tubes, are often to be met with united in one.

631. The small tubes are tubes composed of a succession of elongated cells united, like those of the cellular tissue. Individually they may be compared to the stem of the grasses, which is formed of several internodia, separated by transverse diaphragms; and collectively to a united assemblage of parallel and collateral reeds.

632. Pores are small and minute openings of various shapes and dimensions, that seem to be destined to the absorption, transmission, or exhalation of fluids. They are distinguishable into the following two sorts: perceivable pores and imperceivable pores. The perceivable pores are either external or internal, and are the apertures described by Hedwig as discoverable in the network constituting the epidermis. The imperceivable pores are pores that are not distinguishable by the eye, unless assisted with the best glasses; but they are supposed to exist by the various experiments, and lately been ably delineated and described by A. T. Thomson, in his Lectures on Botany. (Vol. i. p. 605.)

633. Gaps, according to Mirbel, are empty, but often regular and symmetrical spaces formed in the interior of the plant by means of a partial disruption of the membrane constituting the tubes or utricle. In the leaves of herbaceous plants the gaps are often interseen by transverse diaphragms formed of a portion of the cellular tissue which still remains entire, as may be seen in the transparent structure of the leaves of lypha and many other plants. Transverse gaps are said to be observable also in the bark of some plants, though very rarely. There are various appendages connected with the elementary organs, such as internal glands, internal pubescence, &c.: the latter occurs in dissecting the leaf or flower-stalk of symphaca lutea.
635. As plants are not merely organised beings, but beings endowed with a species of life, absorbing nourishment from the soil in which they grow, and assimilating it to their own substance by means of the functions and operations of their different organs, it is plain that no progress can be made in the explication of the phenomena of vegetable life, and no distinct conception formed of the rationale of vegetation, without some specific knowledge of the primary principles of vegetables, and of their mutual action upon one another. The latter requisite presupposes a competent acquaintance with the elements of chemistry; and the former points out the necessity of a strict and scrupulous analysis of the several compound ingredients constituting the fabric of the plant, or contained within it.

636. If the object of the experimenter is merely that of extracting such compound ingredients as may be known to exist in the plant, the necessary apparatus is simple, and the process easy. But if it is that of ascertaining the primary and radical principles of which the compound ingredients are themselves composed, the apparatus is then complicated, and the process extremely difficult, requiring much time and labor, and much previous practice in analytical research. But whatever may be the object of analysis, or particular view of the experimenter, the processes which he employs are either mechanical or chemical.

637. The mechanical processes are such as are effected by the agency of mechanical powers, and are often indeed the operation of natural causes; hence the origin of gums and other spontaneous exudations. But the substances thus obtained do not always flow sufficiently fast to satisfy the wants or necessities of man. And men have consequently contrived to accelerate the operations of nature by means of artificial aid in the application of the wimple or axe, widening the passages which the extraneous fluid has forced, or opening up new ones. But it more frequently happens that the process employed is wholly artificial, and altogether effected without the operation of natural causes. When the juices are enclosed in vesicles lodged in parts that are isolated, or may easily be isolated, the vesicles may be opened by means of rasps or graters, and the juices expressed by the hand, or by some other fit instrument. Thus the volatile oil may be obtained that is lodged in the rind of the lemon. When the substance to be extracted lies more deeply concealed in the plant, or in parts which cannot be easily detached from the rest, it may then become necessary to pound or bruise the whole, or a great part of the plant, and to subject it, thus modified, to the action of the press. Thus seeds are sometimes treated to express their essential oils. And if by the action of bruising or pressing heterogeneous ingredients have been mixed together, they may generally be separated with considerable accuracy by means of decantation, when the substances held in suspension have been precipitated. Thus the acid of lemons, oranges, gooseberries, and other fruits, may be obtained in considerable purity, when the mucilage that was mixed with them has subsided.

638. The chemical processes are such as are effected by the agency of chemical powers, and may be reduced to the following: distillation, combustion, the action of water, the action of acids and alkalies, the action of oils and alcohols, and lastly fermentation. They are much more intricate in their nature than the mechanical processes, as well as more difficult in their application.

639. Of the products of vegetable analysis, as obtained by the foregoing processes, some consist of several heterogeneous substances, and are consequently compound, as being capable of further decomposition; and some consist of one individual substance only, and are consequently simple, as being incapable of further decomposition.

Sect. I. Compound Products.

640. The compound products of analysis are very numerous in themselves, and much diversified in their qualities. They are gum, sugar, starch, gluten, albumen, fibrina, extract, tannin, coloring matter, bitter principle, narcotic principle, acids, oils, wax, resins, gum resins, balsams, camphor, caoutchouc, cork, woody fibre, sap, proper juice, charcoal, ashes, alkalies, earths, metallic oxides.

641. Gum is an exudation that issues spontaneously from the surface of a variety of plants, in the state of a clear, viscid, and tasteless fluid, that gradually hardens upon being exposed to the action of the atmosphere, and condenses into a solid mass. It issues copiously from many fruit-trees, but especially from such as produce stone-fruit, as the plum and cherry-tree. From plants or parts of plants containing it, but not discharging it by spontaneous exudation, it may be obtained by the process of maceration in water. It has been found by chemists to consist of several varieties, known by the names of gum arabic, gum tragacanth, cherry-tree gum, and mucilage. Gum arabic, which is the most plentiful of all the gums, is the produce of the mimosa nilotica, a native of the interior of Africa and of Arabia; whence its name. When pure, it is colorless and transparent, though sometimes it is tinged with yellow, varying in its specific gravity from 1300 to 1400. (Davy's Agric. Chem., lect. iii.) It is insoluble in alcohol; but is readily soluble in...
water; and if the solution is exposed to the action of the atmosphere, the water is gradually evaporated, and the gum again left in a solid mass. According to the analysis of Gay Lussac and Thénard, it consists of the following elements, in the following proportions, 100 parts being the integer: carbon 42.25; oxygen 57.75. Sugar is used in the manufacture of starch; to this end it is heated with a small quantity of lime or soda, separated from the mass, and residue, 100. Gum tragacanth is the produce of the astragalus tragacantha, a thorny shrub that grows in the islands of the Levant. It is less transparent than gum arabic, and not so easily dissolved in water. Cherry-tree gum is obtained from the pulp of that name, and is of the same genus, as its name, from all trees with stone-fruit, from which it exudes spontaneously and in great abundance. It differs from gum arabic and tragacanth in its gelling in larger masses, and being more easily melted. Muelago is found chiefly in the roots and leaves of plants, particularly such as are bulbous and succulent; the bulbs of the hyacinth and onion, with those of thistles, clovers, flax-seeds, &c., as well as in flowers, and is to be obtained only by maceration in water, from which it is separated by means of sulphuric acid.

The uses of gum are considerable. In all its varieties it is capable of being used as an article of food, and is highly nutritive, though not very palatable. It is also employed in the arts, particularly in calico-printing, in which it gives consistence to the other colours, and to prevent them from spreading. The botanist often uses it to fix his specimens upon paper, for which purpose it is very well adapted. It forms likewise an ingredient in ink; and in medicine it forms the basis of many mixtures, in which its influence in soothing and emollient is seen and experienced.

642. Sugar is the produce of the saccharum officinarum. (fig. 53.)

The canes or stems of the plant, when ripe, are bruised between the rollers of a mill, and the expressed juice is collected and put into large boilers, which are kept hot by the application of quick steam. It is composed of a strong ley of ashes, to neutralise its acid, and is then made to boil. The steam which gathers on the top during the process of boiling is carefully cleared away; and when the juice has been boiled down to the consistency of a syrup, it is drawn off and allowed to cool in vessels which are placed above a cistern, and perforated with small holes, through which the impure and liquid part, known by the name of mashes, is remaning. A portion of this is converted into a mass of small and hard granules of a brownish whitish color, known by the designation of raw sugar, which, when imported into Europe, is further purified by an additional process, and converted by filtration or crystallisation into that called loaf sugar, or refined sugar, or sugar-refined. Sugar thus obtained has a sweet and juicy taste, but is without smell. According to Dr. Thomson its specific caloric is 1085, its specific gravity 1-0575, and its constituent elements are oxygen 49.7; carbon 50.3; hydrogen 6.05; total 100. The juice of the seer sahcanum, or American maple, yields sugar in such considerable abundance as to make it an object with the North American farmer to manufacture sugar from it. A hollow is bored in the trunk of the vegetable plant, from early in the spring, for the purpose of extracting the sap; of which a tree of ordinary size, that is, of from two to three feet in diameter, will yield from one hundred and fifty to two hundred pints and upwards, in a good season. The sap is rich in neutral and alkaline deposits, by evaporation, natural ornamentation, crystals of sugar, &c., according to the proportion of about a pound of sugar to forty pints of sap. It is not materially different in its properties from that of the sugar-cane. The juice of the grape, when ripe, yields also a sugar by evaporation and the action of pot-ashes, which is known by the appellation of grape sugar, of grapes, and has been lately employed in France as a substitute for colonial sugar, though it is sweeter and more agreeable to the taste.

The root of beta vulgaris, or common beet, yields also, by boiling and evaporation, a sugar which is distinguished by a peculiar and slightly bitter taste, owing perhaps to the presence of a bitter extractive matter which has been found to be one of the constituents of the beet. Sugar has been extracted from the following vegetables also, or from their productions: from the sap of the birch, sycamore, bamboo, maize, parsnip, cow-parsnip, American aloe, dulse, walnut-tree, and cocoa-nut-tree; from the fruit of the common arbutus, and other sweet-tasted fruits; from the roots of the turnip, carrot, and parsley; from the rhizomes of certain species of plants from the nectarine, chestnut, and from other cousins.

643. The utility of sugar, as an aliment is well known; and it is as much relished by many animals as by man. By bees it is sipped from the flowers of plants, under the modification of nectar, and converted into honey, to be relished by the bee himself, and also by many insects, even by many birds. By man it is now regarded as being altogether indispensable, and though used chiefly to give relish or seasoning to food, is itself highly nutritive. It is also of much utility in medicine, and celebrated for its anaodyne and antiseptic qualities, as well as thought to be peculiarly efficacious in preventing diseases by worms.

644. Starch. If a quantity of wheaten flour is made into a paste with water, and kneaded and washed under the action of a jet, till the water runs off colorless, part of it will be found to have been taken up and to be still held in suspension by the water, which will, by-and-by, deposit a sediment that may be separated by decantation. This sediment is starch, which may be obtained also immediately from the grain itself, by means of a process well known to the manufacturer, who renders it finally fit for the market by washing and edulcorating it with water, and afterwards drying it by a moderate heat. Starch, when thrown upon red hot iron, burns with a kind of explosion, and leaves scarcely any residuum behind. It has been found by the analysis of Gay Lussac and Thénard, to be composed of carbon 43.55; oxygen 40.68; hydrogen 6.77; total 100. This result is not very widely different from that of the analysis of sugar, into which it seems, starch may be converted by diminishing the proportion of its carbon, and increasing the quantity of oxygen and hydrogen. This is exemplified in the case of the malting of barley, which contains a great proportion of starch, and which absorbs during the process a quantity of oxygen, and evolves a quantity of carbonic acid; and accordingly part of it is converted into sugar. Perhaps it is thus applied also in the case of the freezing of potatoes, which acquire in consequence a sweet and sugary taste, and are known to be of great deal of starchy plants, which may be obtained as follows: let the potatoes be taken and grated down to a pulp, and the pulp placed upon a fine sieve, and water made to pass through it: the water will be found to have carried with it an infinite number of particles, which will again be precipitated by a little ground powder, followed by decantation; which powder is starch, possessing all the essential properties of wheaten starch. It may be obtained from the pith of several species of palms growing in the Moluccas and several other East Indian islands, by the following process: the stem, being first cut into pieces of five or six feet in length, is split longitudinally so as to expose the interior; it is now tied up, and placed in a vessel containing gently boiling water; it is well stirred up, deposits at length a sediment that is separated by decantation, and is the starch which the pith contained, or the sago of the shops.
646. According to Parmeater, starch may be extracted from a number of plants; as artemio kapu, atropa belladonna, polygonum bistorta, bryonia alba, colchicum autumnale, spiraea filipendula, ramunculus bulbosus, scrophularia nodosa, sambucus ebulus and nigra, orchis morio and mascula, imperatoria oestruthium, hyoscyamus niger, rumex obtusifolius, acutus, and aquarids, arum maculatum, iris pseudacorus and peperomia obtusifolia. In them the following seeds: wheat, barley, oats, rice, maize, millet-seed, chestnut, horse-chestnut, peas, beans, acorns.

647. Starch is an extremely nutritive substance, and forms one of the principal ingredients in almost all articles of animal or vegetable origin. It is of two kinds: one or the native state in which nature presents it; but man prepares and purifies it so as to render it pleasing to his taste, and uses it under the various modifications of bread, pastry, or confectionary. Its utility is also considerable in medicine and in the arts; in the preparation of enzylene and strengthening medicaments, and in the composition of cements; in the clearing and stiffening of linen; and in the manufacture of hair-powder.

648. Glutin is that part of the paste formed from the flour of wheat that remains unaffected by the watery washes to which it is subjected in the process of washing and cleaning. It is a tough and viscid solution of a dull white color, without taste, but of a very peculiar smell. It is soluble in the acids and alkalis, but insoluble in water. Glutin has been detected, under one modification or other, in a very considerable number of vegetables or vegetable substances, as well as in the flour of wheat. Hence, the young wheat or 'green wheat' contains glutin; and it seems to be a constant property of all plants, either in the leaves or fruits.

651. Albumen, which is a thick, glary, and tasteless fluid, resembling the white of an unboiled egg, is a substance that has been but lately proved to exist in the vegetable kingdom. It has been thought to be found only in the egg, particularly the yellow or yolk. It is a thick and transparent liquid, of a dull white color, without taste, but of a very peculiar smell. It is soluble in the acids and alkalis, but insoluble in water. Albumen has been detected, under one modification or other, in a very considerable number of vegetables or vegetable substances, as well as in the flour of wheat. Hence, the young wheat or 'green wheat' contains albumen; and it seems to be a constant property of all plants, either in the leaves or fruits.

652. Extract when vegetable substances are macerated in water, a considerable portion of them is dissolved; and if the water is again evaporated, the substance held in solution may be obtained in a separate state. But the process is not without objection, and it can be shown that extraction is not the precise principle in every different plant, but will vary in its character according to the specie producing it, or the soil in which the plant has grown, or some other accidental cause. Its disadvantage is that soluble in water; but becomes afterwards insoluble in consequence of the absorption of oxygen from the atmosphere. It is soluble; and it unites with alkalis, and forms compounds which are soluble in water. When distilled it yields an acid fluid impregnated with ammonia, and seems to be composed principally of hydrogen, oxygen, carbon, and a little nitrogen. Extract, or the extractive principle, is found in a greater or less proportion in almost all plants whatever, and is very generally an ingredient of the sap and bark, particularly in barks of an astringent taste. But still it is not exactly the same in all individual plants, even when separated as much as possible from the extraneous matter. It may be regarded as constituting several different species, of which the following are the most remarkable:

Extract of malt. This extract is obtained from the fermentation of malt or cantharum in cold water. Its color is a pale brown; and its taste slightly astringent. It is present in the solution by the union of carbonic acid with the sugar, it yields, by distillation carbonic and carbamide hydrogene gas, leaving a portion of water.

Extract of hemp. This extract is obtained from the infusion of the dried leaves of cannabissa in alcohol. The color of the infusion is brownish, the taste slightly bitter, and the smell aromatic. It is precipitated from its solution by the union of carbon dioxide with the sugar, it cools, consumes, with a thick smoke and aromatic color, leaving behind a soapy charred.

Extract of tobacco. This extract is obtained from an infusion of the dry or good part of canna in cold water, its color is a pale brown; and its taste slightly astringent. It is precipitated in its solution by the union of ammonia and the sugar, it cools, consumes, with a thick smoke and aromatic color, leaving behind a soapy charred.

Extract of opium. This extract was obtained by Fourcroy, by evaporating a decoction of the bark of the opium plant, St. mandragora, in water, and again dissolving it in alcohol, which was then evaporated, and these operations repeated by him several times, it yields a very dark brown color. It is soluble in cold water, but very soluble in boiling water, its proportion is 16 per cent. It is precipitated in its solution by the union of oil-water, in the form of a red powder; and when dry it is black and brittle, breaking with a polished fracture.

Extract of tannin. This extract is obtained in great abundance from the bark of creus satibus, which are almost wholly soluble in water.
655. The juice of all vegetable narks is that which is known by the name of tannin. It is the product of the bark of trees belonging to the genus Tannina, a shrub which is cultivated for the sake of the dye it affords. Tannin is also derived from the East Indies juniper at the time of its budding in about six months, when its leaves are gathered and immersed in vessels filled with water till fermentation takes place. The water then becomes opaque and green, emitting an odor like that of volatile alkali, and evolving bubbles of carbonic acid gas. When the fermentation has been continued long enough, the liquid is decanted and put into other vessels, where it impregnated all the vessels with tannin. Water is now poured in, and the flakes are precipitated in the form of a blue powdery sediment, which is dissolved by dilution; and when after boiling made up into small lumps and dried in the shade, is the indigo of the shops. It is insoluble in water, but is taken up by slightly solublesubstances; the most potent is sulphuric acid, with which it forms a fine blue dye, known by the name of indigo blue. It affords by dissilation carbonic acid gas, water, ammonium, some oily and acid matter, and much charcoal; whence its constituent principles are one or more of the latter, and less probably, gum-arabic, oxygen, hydrocarbon, sulphur, etc. Indigo may be procured also from several other plants besides indica, but they are not so valuable, and particularly those of the mussor, a plant indigenous to Britain, and thought to be the plant of the ancient time, of which the ancients made use. They have had the naked bodies, to make them look terrible to their enemies. If this plant is digested in alcohol, and the solution evaporated, whilst or when several parts of bark are rescuing starch, will be left behind; but grains, which are indigo, become gradually blue, the action of the atmosphere. The indigo of India therefore is owing to its combination with oxygen.

656. The principal red colors are such as are found to exist in the root, stem, or flower, of the following plants: rubia tinctoria, lichen roccella and parasil, carthamus tinctorius, cascara sagrada, persicaria bistorta, quassia, etc.

657. Yellow, which is a color of very frequent occurrence amongst vegetable products, and the most prominent is that which is extracted for the purpose of dyeing, from a variety of plants. It is extracted from the root of sophora fataea, Lindi, and is known as its dried stamens. The coloring matter is precipitated by means of alum, and is much used in dyeing wool, silk, and cotton. It is also used in the preparation of yellow Hanks from the murr tinctoria, or annatta (fie. 54), serrata tinctoria, gentis tinctoria, rubus euterus, thomassus infectus, and quercus tinctoria, or quercitron, the bark of which last affords a rich and permanent yellow that is at present much in use.

658. The brown coloring matter of vegetables is very abundant, particularly in the acrid, or narky, plants. It is obtained from the root of the walnut-tree, and rind of the walnut; as also from the same and elder, but chiefly from nut galls, which are exceedingly formed upon the leaves of a species of quercus, indigenous to the south of Europe, in consequence of the puncture of insects. The last in quality are brought from the Levant. They are sharp and bitter to the taste, and extremely astringent to the texture, and are used by the Arabs as a unguent and for the ground or grated into a powder. The decoction stirs, with the solution of iron, a deep black, that forms the basis of ink, and of most dark colors used in dyeing cloths.

659. Tannin. If a quantity of pounded nut-galls, or bruised seeds of the grape, is taken and dissolved in cold water, and the solution evaporated to dryness, there will be left behind a brittle and yellowish solution of a highly astringent taste, which substance is tannin, or the tanning principle. It is soluble both in water and alcohol, but insoluble in ether. When the salts of iron it strikes a black. And when a solution of a powder of bark is suspended in the solution of a nut galls, it is dissipated down in combination, and form an insoluble precipitate. When tannin is subjected to the process of distillation, it yields charcoal, carbonic acid, and inflammable gases, with a minute quantity of volatile alkali, and seems to consist of the same as the acetate or extract, from which, however, it is distinguished by the peculiar astringent property of its action upon gelatine. Tannin may be obtained from a great variety of other vegetable also, as well as those already enumerated, but chiefly from their bark; and of bars, chiefly from those that are astringent to the taste. The following table exhibits a general view of the relative value of tannin, as acquired by Humphry Davy. It gives the average obtained from 480lb. of the entire bark of a middle-sized tree of the several different species, taken in the spring, when the quantity of tannin is the largest.

660. Tannin is of the very utmost utility in its application to medicine and the arts; being regarded by chemists as the general astringent principle of vegetable purgatives of Peruvian bark, so celebrated as a febrifuge and antiscorbutic, are supposed to depend upon the quantity and quality of its tannin. In consequence of its peculiar property of forming an insoluble compound with gelatine, the hides of animals are converted into leather, by the important art of tanning. The bark of the oak-tree, which contains tannin in great abundance, and is most generally used by the tanner. The hides to be thus tanned are covered for the process by steeping them in lime-water, and scratching off the hair and cuticle. They are then soaked first in weaker infusions, and afterwards in stronger infusions of the bark, till at last they are completely impregnated. This process requires a period from ten to eighteen months. As the hides are thick; and four or five pounds of bark are needed in an average to form one pound of leather.

661. Bitter principle. The taste of many vegetables, such as those employed in medicine, is extremely bitter. The juice of the fruits, the roots of common gentian, the bark and wood of common broom, the calyx, and the leaves of the hop, and the leaves and flowers of chamberion, may be quoted as examples. This bitter taste has been thought to be owing to the presence of a peculiar substance, different from every other vegetable substance, and has been distinguished by the name of the bitter principle. When water has been digested for some time over quassia, its color becomes yellow, and its contents with the addition of a substance of a slight degree of transparency, that continues for a time dullish, but becomes afterwards brittle. This substance Dr. Thomson regards as the bitter principle in a state of purity. It is soluble in water and in alcohol; but the solution is not much affected by rennet. Nitrate of silver and acerate of lead are the only two which occasion a precipitation. The bitter principle is of great importance, not only in the practice of medicine, but also in the art of brewing; its influence being that of checking fermentation, preserving the fermented liquor, and when the bitter of the hop is used, communicating a peculiar and agreeable flavor. The bitter principle appears to consist particularly carbon, hydrogen, and oxygen, with a little nitrogen.

662. Narcotic principle. There is a species of medical preparations known by the name of narcotics, which have the property of inducing sleep; and if administered in large doses, of occasioning death. They are obtained from the milky and proper juice of some vegetable and animal substances, which have been supposed to contain in their composition some common ingredient, which chemists have agreed to designate by the name of the narcotic principle. It exists in great abundance in opium, which is the concrete juice of papaverum album, or the white poppy, from which it is obtained pure, in the form of white crystals. It is also obtained from the distilled water and in alcohol, as well as in all acid menstrua; and it appears that the action of opium on the animal subject depends on this principle. When diluted it emits white vapors, which are condensed into a yellow oil. Some water and carbonic acid, ammonia, and carborised hydrocarbons, are formed on the dissolution of an opium brown and a black charcol left behind. Many other vegetable substances besides opium, possess narcotic qualities, though they have not yet been minutely analysed. The following are the most remarkable: the insipid juice of lettuce, which resembles opium much in its appearance, is obtained by the same means, and possesses the same medical virtues the leaves of stropharia bulbilum, or deadly nightshade, and indeed the
664. *Oxyacetic acid.* If the expressed juice of the oxalis acetosella is heated, it decomposes oxygen, and forms a liquid of a yellowish color and saltish taste, which is known by the name of the acidum carbinolicum, and which the acid may be obtained pure by processes well known to the chemist. It is not used in medicine or the manufacture of drugs, except in the form of its salt, which is employed to make a sort of lemonade, and to discharge stains of blood. When it has been obtained, it must be kept in a leaden acidum, in the several species of rame, and in the presence of pure air.

665. *Carboxylic acids.* The oxalic acid, or vinegar, which is generally manufactured from wine in a certain stage of fermentation, is often converted into the form of several trees, as analysed by Vauquelin; and also in the acid juice of the malva sylvestris, of which it forms a constant part. It was obtained also by Scheele from the sap of the samambuca nigrum; and is consequently to be regarded as a native acid. It is distinguished from other vegetable acids by its fuming soluble salts with the alkalies and earths.

666. *Ethanolic acids.* From the rind of the olive it is extracted in the juice of lemon. Its taste is very sour in a state of purity, but exceedingly mild when mixed with water. Its acid is titrated in water, it yields carbonic acid gas and carbonated hydrogen gas, and is reduced to a chemically unstable state. It is very soluble in alcohol and water with time it forms a salt insoluble in water. It has been found united with other acids in the following vegetable substances, both in and out of the berries and in the berries of vaccinium oxyccoccus, and virus idea, prunus palaestina; it is not formed in the mastic and gums and in the gums also in many other fruits, mixed with other acids.

667. *Malic acid.* It has been found chiefly in the juice of unripe fruits, whence it derives its name. It is also found in the juice of barberries, alderberries, gooseberries, plums, and Erica carnea.

668. *Gallic acid.* (Gallic acid, as it is obtained in the greatest abundance in the acorns of the oak, which may be either whole or when it is made by extracting a quantity of the powder of nutmegs, and then dissolving it in a glass of water, the whole and forms crystal of an octahedral figure. Its taste is astrinquent and astringent. It strongly redoubles veget-

669. It appears that all vegetable acids contain carbon, oxygen, and hydrogen, in one proportion or other; and that the prussic acid contains also a portion of nitrogen. The gallic acid contains more of carbon than any other vegetable acid, and more of oxygen than the oxalic.

670. *Vegetable oils.* The first vegetable oil extracted in the world was obtained from animal substances. But it has been proved to exist in vegetable substances also, and is procured by distilling laurel leaves, of which there are two sorts, one red and the other white. When pure it exists in the form of a colorless fluid, with an odor resembling that of garlic, and is converted into vegetable blues. But it is characterized by its property of being fixed in the air, and is dissolved in water, and is used in pharmacy, in the preparation of lozenges and other medicines.

671. *Prussic acid.* The prussic acid is generally classed among the vegetable acids, which is accounted for in its appearance from animal substances. But it has been proved to exist in vegetable substances also, and is procured by distilling laurel leaves, of which there are two sorts, one red and the other white. When pure it exists in the form of a colorless fluid, with an odor resembling that of garlic, and is converted into vegetable blues. But it is characterized by its property of being fixed in the air, and is dissolved in water, and is used in pharmacy, in the preparation of lozenges and other medicines.

672. *Vegetable oils.* The first vegetable oil extracted in the world was obtained from animal substances. But it has been proved to exist in vegetable substances also, and is procured by distilling laurel leaves, of which there are two sorts, one red and the other white. When pure it exists in the form of a colorless fluid, with an odor resembling that of garlic, and is converted into vegetable blues. But it is characterized by its property of being fixed in the air, and is dissolved in water, and is used in pharmacy, in the preparation of lozenges and other medicines.

673. *Vegetable oils.* The first vegetable oil extracted in the world was obtained from animal substances. But it has been proved to exist in vegetable substances also, and is procured by distilling laurel leaves, of which there are two sorts, one red and the other white. When pure it exists in the form of a colorless fluid, with an odor resembling that of garlic, and is converted into vegetable blues. But it is characterized by its property of being fixed in the air, and is dissolved in water, and is used in pharmacy, in the preparation of lozenges and other medicines.

674. *Vegetable oils.* The first vegetable oil extracted in the world was obtained from animal substances. But it has been proved to exist in vegetable substances also, and is procured by distilling laurel leaves, of which there are two sorts, one red and the other white. When pure it exists in the form of a colorless fluid, with an odor resembling that of garlic, and is converted into vegetable blues. But it is characterized by its property of being fixed in the air, and is dissolved in water, and is used in pharmacy, in the preparation of lozenges and other medicines.
677. Volatile oils. Volatile oils, which are known also by the name of essential oils, are of very common occurrence in the vegetable kingdom, and are found in almost all the different organs of the plant. They are volatile because they constitute a fragrant and aromatic odor, with a taste somewhat acrid. The roots of inula helenium, genista canariensis, and a variety of other plants, contain essential oils. They are found also in the lark of laurus cinnamomum, of laurus sasafras, and pine; in the leaves of labiate plants, such as mint, rosemary, syringa, and mandarinium; and of plants with compound flowers, such as rowanwood. They are found also in the flower itself, as in the flowers of cornelian, and the rose; and in the fruit, as in that of pepper and ginger, and in the external integuments of many seeds, but never in the cotyledon. They are extracted by means of heat, sometimes the heat of strong acid, or occasionally by the direct application of heat. The plant possessing a peculiar odor possesses also a peculiar and volatile oil. The aroma of plants, therefore, or the substance from which they derive their odor, and which is cognizable only by the sense of smell, is perhaps merely the more volatile and evaporable part of their volatile oil, disengaging itself from its combination with the oil, and rather acid taste. They are soluble in alcohol, but not readily converted into soaps by alkalies. They are very inflammable, and are volatilised by a gentle heat. Like fixed oils, their specific gravity is generally less than that of water, on the surface of which they float. When subjected to the action of a falling weight, it is found that an oil can be made to sink by causing a current of air to be blown under it, consequently sink. They are much in request on account of their agreeable taste and odor, and are prepared and sold by apothecaries and perfumers, under the name of distilled waters or essences; as well as employed also in the manufacture of varnishes and pigments.

678. Wax. On the upper surface of the leaves of many trees there may often be observed a sort of varnish, which, when separated by certain chemical processes, is found to possess all the properties of bees' wax, and is consequently a vegetable wax. It exudes, however, from several other parts of the plant besides the leaf, and assumes a more waxy and concrect form, as on the catkins of the poplar, the alder, and the fir; from the fruit of the myrica cerifera and croton seifertius; but particularly from the anthers of the flowers, from which it is probable that the bees extract it unaltered. It was the opinion of Reaumur, however, that the pollen undergoes a digestive process in the stomach of the bee before it is converted into wax, and it is by a law to prove that the vegetable wax is derived from the honey extracted by the bee, and not from the pollen. It is found also in the interior of many seeds, from which it is extracted, by means of heating them and boiling them in water. The wax is melted and swims on the top. Wax, when pure, is of a whitish color, but without taste and without smell. The smell of bees' wax is of a peculiar nature, and is composed of its color. Figs, for example, are annoyed by the presence of bees' wax, and are not readily converted into soaps by alkalies. They are very inflammable, and are volatilised by a gentle heat. Like fixed oils, their specific gravity is generally less than that of water, on the surface of which they float. When subjected to the action of a falling weight, it is found that an oil can be made to sink by causing a current of air to be blown under it, consequently sink. They are much in request on account of their agreeable taste and odor, and are prepared and sold by apothecaries and perfumers, under the name of distilled waters or essences; as well as employed also in the manufacture of varnishes and pigments.

679. Wax possesses all the essential properties of a fixed oil. But fixed oils have the property of becoming a gum and of assuming a waxy appearance when long exposed to the air, in consequence as it seems, of the absorption of oxygen. Wax therefore may be considered as a fixed oil rendered concrete, perhaps by the absorption of oxygen during the progress of vegetation. But if this theory is just, the wax may be considered to be more considerable according to the states of oxygen it has absorbed. The time is the subject of some controversy. This phenomenon was first observed by the daughter of the celebrated Linnaeus, and is explained by supposing the partial and temporary atmosphere to contain a proportion of wax exuded from the plant, and afterwards reduced to vapor by the action of the sun. The result of its combustion in oxygen gas was, according to La Volpier, carbonic acid and water, in such proportion as to lead him to conclude that 100 parts of wax are composed of 82.28% of carbon and 17.72% of hydrogen. But owing to the little action of oxygen upon it, there seems reason to believe that it contains also oxygen as an ingredient.

680. The butter of cacao is extracted from the seeds of the theobroma cacao or chocolate plant (Fig. 554), either by boiling them in the water, or by subjecting them to the action of the press after having exposed them to the vapor of boiling water. The butter of cacao is found in the fruit of the cocoa meleira or cacao-nut tree. It is expressed from the pulp of the nut, and is even said to separate from it when in a fluid state, as cream separates from milk.

681. Resins. Resins are volatile oils, rendered concrete by the absorption of oxygen, or rather perhaps by the abstraction of part of their hydrogen, and acquiring a light or pearly dream, and a transparent character, and being generally yellowish. Their taste is somewhat acid; but they are without smell when pure. Their specific gravity varies from 1.0490 to 1.2580. They are used in the arts of electricity, and when excited by friction their electricity is negative. The species of resins are numerous.

682. Rosin is a species of resin, of which there are several varieties. — From different species of the pine, larch, fir, and spruce, though forming the same resin, there is an extrication of it generally aided by means of incisions, and it requires no other process than a process from which it is obtained. If it is obtained from the pine sylvestris it is termed taipean, or tajpean; from the spruce it is termed spruce tar, or spruce tars. From amarys baldovinum, found on trees at a height of 3000 or 4000 feet above the sea, it is termed amarys or amarys tars. A resin is obtained from the amarys baldovinum, by spontaneous exudation.

683. pitch and tar are manufactured from the resinous juice of the fir. The trunk is cut or split into pieces of a convenient size, which are piled together, and covered with earth. When dry, they are then set on fire, and the resins are exuded, being prevented from escaping by the introduction of steam by means of the norf, is precipitated and collected in a vessel beneath. It is partly converted into an empyreumatic oil, and is now tar, which, by being further impregnated, is converted into pitch.

684. Mastic is extracted from the pistacia lentiscus.

685. Turpentine is obtained from the amarys baldovinum, by spontaneous exudation.

686. Haw is the product of the fagara octandra and populus bahamensis.

687. Labdanum is obtained from the cistus creticus.
681. *Opobacusmanum,* or *balsam of Gilzard,* which has been so much famed for its medical virtues, is the produce of the amaryllis *Nolutes maritima,* found in Indian and African countries, but it is so much valued by the Turks that its importation is prohibited by law. It is also mentioned in the Bible as *sphage,* in Scripture. Fliny says it was first brought to Rome by the general of the Greeks. It is thought to be a species of *Galea.*

682. *Blood-root,* or *the blood-root,* is an herb of the *Rancunculaceae,* a native of New Holland, and found in great abundance about Botany Bay.

683. *Green resin* consists of the coloring matter of the leaves of trees, and of almost all vegetables. It is insoluble in water, but soluble in alcohol, or, with other solvents. When it is dissolved in alcohol, it assumes the color of a withered leaf, and exhibits the resinous properties more distinctly.

684. The use of resins in the arts is very considerable; but their medical virtues are not quite so great as has been generally supposed. They are employed in the arts of painting, varnishing, embalming, and making varnish and varnished paper, and they furnish us with two of the most important of all materials to a naval power, pitch and tar.

685. Gum-resins. This term is employed to denote a class of vegetable substances, which have been regarded by chemists as consisting of gum and resin. They are generally contained in the proper vessels of the plant, whether in the root, stem, branches, leaves, flowers, or fruit. But there is this remarkable difference between resins and gum-resins, that the latter have never been known, like the former, to exude spontaneously from the plant. They are obtained by means of bruising the parts containing them, and compounding them, in the state of an emulsion, generally white, but sometimes of a different color; or they are obtained by means of incisions from which the juice flows. This juice, which is the proper juice of the plant, is then exposed to the action of the sun, by which, in warm climates, it is condensed and inspissated, and converted into the gum-resin of commerce. Gum-resins, in this state, have general properties, and less value than the true gums; this is sometimes astringent, and a bitter and nauseous taste. They are partially soluble both in water and in alcohol. When heated, they do not melt like the resins, nor are they so combustible. But they swell and become like a flame, and if blown into a flame, they yield a flame which is combined with an acid, and has a bulky charcoal. The principal species of gum-resins which have been hitherto applied to any useful purpose are:

686. *Gallinum,* obtained from the stem of the gallinum galbanum. *Ammoniac,* brought from Africa in the form of small tears; these resins are red, and it is thought to be a species of *Convulvus.*

687. *Dag.* This is the product of the rhus copallinum, a tree which is found in North America. *Ammoniac,* found in the *nymphea canulina,* or Locust-tree, a native of North America.

688. *Gamboge,* obtained from the *babulum gamboge,* a native of the East Indies.

689. Upon the epidermis of the leaves and fruit of certain species of plants, there is to be found a fine, soft, and glabrous powder. It is particularly observable upon cabbagel-leaves, and upon plants which they have contaminated with their juice. It is known to gardeners by the name of *tobacco.* It is easily raised off by the fingers, and when soaked under the microscope, it seems to be composed of small opaque and unpolished granules, somewhat elongated or oblong; they are white in color, have a great magnifying power as it appears transparent. When rubbed off, it is again re-produced, though slowly. It resists the action of dew and rain, and is not immediately volatilized. But it is soluble in spirits of wine; from which circumstances it has been suspected, with some probability, to be a resin.

690. Balsams. The substances known by the name of balsams are resins united to the benzoic acid. They are obtained by means of incisions made in the bark, from which a viscous juice exudes, which is afterwards inspissated by the action of the fire or air, or they are obtained by means of boiling the part that contains them. They are thick and viscous juices, but become readily concrete. They are brown or colors, and have a very specific and strong odor, which becomes more tolerable in the air after becoming concrete. They are insoluble in water, but boiling water extracts part of their acid; they are soluble in the alkalies and nitric acid. When heated and melted, evolving a white and odorous smoke. The principal of the balsams are the following: *benzinon, storax, stygian, incense gum of toluba,* and *incense gum of Peru.*

**Balsam of tolu** is obtained from the balsam tree.*

**Inka of Peru** is obtained from the myroxylon peruifera.

691. *Myrrh,* the plant yielding which grows in Abyssinia and Arabia. Bruce says it belongs to the genus mimusol; but however this may be, myrrh is the juice of the plant concreted in the form of a pearly white color; it is odor of a pungent and agreeable, and its taste bitter: it is employed in medicine, and is used in embalming. *Styrax* is obtained from a species of *Styrax.*

692. *Aromabalsam,* a substance which is well known for its strong and balsam smell, is obtained from the *solanum accenticaule.* At four years of age, it becomes a very hard and tenacious root. It is clear, and the extremity cut off; a milky juice exudes which is very agreeable, but not strong; it is more bitter than the former, and more intense extract. The process is continued till the root is exhausted. The juice which has been collected seen concretes, and contains aromatic. It is brought to Europe in small aggregated grains of different colors, white, red, yellow, and black, but latterly, and its smell insupportably bad; the *Indians use it as a vomition for their gout, and a stimulant for the gods.* In Europe, it is used in medicine as an antispasmodic.

693. *Grape juice* is obtained from the *baebulum gamboge.* *Indica of Peru* is obtained from the *myroxylon peruifera.*
in a vessel containing oxygen gas, the pellicle is formed sooner. If oxymuriatic acid is poured into the milky juice, the caoutchouc precipitates immediately. This remark renders it probable that the formation of the caoutchouc is partly owing to the absorption of carbonic acid; caoutchouc, when pure, is of a white color, without taste and without smell. The black color of the caoutchouc of commerce is owing to the method of drying, the different layers upon the moulds on which they are spread. They are dried by being exposed to a current of hot air, partly in the air, partly in a kiln. The caoutchouc is therefore found in different layers. It is soft and pliable like leather, and extremely elastic, so that it may be stretched to a very great length, and still recover its former size. Its specific gravity is 0.6355. Gough, of Manchester, has made some curious and important experiments on the connection which exists between the elasticity of caoutchouc, and its plasticity, from which it results that ductility as well as fluidity is owing to latent heat. Caoutchouc is not altered by exposure to the air. It is perfectly insoluble in water; but if boiled in water for some time its edges become so soft that they will cement, if pressed and kept for a while closely together, which would not otherwise happen. It is insoluble in alcohol, ether and in volatile spirits. From the action operated upon by acids it is thought to be composed of carbon, hydrogen, oxygen, and azote. It seems to exist in a great variety of plants combined with other ingredients. It may be separated from the berries of the misseltoe by means of nitric acid, or other similar processes. It is procured by other names under different technical names in different parts of the world and inistant. But from these substances it cannot be extracted in sufficient quantities to make it worth the labor. It is applied to a great many useful purposes both in medicine and the arts, to which, from its great plasticity and elasticity, it is uncommonly well adapted. In the countries where it is produced the natives make boots and shoes of it, and often use it as money.

690. Cork. The substance known by the name of cork is the outer and exfoliated bark of the quercus suber or cork-tree, a species of oak that grows in great abundance in France, Spain, and Italy. But to prevent its natural exfoliation, which is otherwise an irregardless and ruinous proceeding, longitudinal incisions are made in the bark from the root to the top of the stem; and a transverse and circular incision at each extremity. The outer layer, which is cork, is then stripped off, and to flatten and reduce it to sheets is put into water and loaded with weights. The tree continues to thrive, though it is thus stripped of its cork. Cork is a light, tough and elastic substance, on account of the following properties:--its color is a sort of light tan. It is very inflammable, and burns with a bright white flame, leaving a black and bulky charcoallish behind. When distilled it yields a small quantity of ammonia. Nitric acid corrodes and dissolves it, changing its color to yellow, and finally decomposes it, separating from it a substance resembling wood or resin. The acid which is thus formed is denominated the suberic acid, and has been proved by the experiments of Lagrange to be an acid of a peculiar nature. It appears probable that cork exists in the bark of some other trees also, as well as the quercus suber. It is a bark of the same kind of the external appearance of cork, which it resembles in its thickness, softness, and elasticity, and in its loose and porous texture, as well as in its chemical properties. Fourcroy seems, indeed, to regard the epidermis of all trees whatever to be a sort of cork, but does not say on what grounds his opinion is founded.

691. Charcoal. As the root, stem, and branches of trees, are designated by the appellation of wood. But the term is too general for the purpose of analytical distinction, as the part designated by it often includes the greater part of the substance that has been already enumerated. It remains, therefore, to be ascertained whether there exist in the tree any individual substance more immediately the fabric of the wood. If a piece of wood is well dried and digested, first in water and then in alcohol, or such other solvent as shall produce no violent effects upon the insoluble parts; and if the digestion is continued till the liquid is no longer colored, and of the plant, the parts of the resinous, and volatile, which constitutes the basis of the wood, and which has been denominated woody fibre. It is composed of bundles of longitudinal threads, which are divisible into others still smaller. It is somewhat transparent. It is without taste and smell, and is not altered by exposure to the atmosphere. It is insoluble in water, in alcohol, and in the purest aqua regia; and decomposition takes place, not by the separation of the oxygen, but by the formation of a new substance, which, when converted in the open air it blackens without melting or frowning, and exhales a thick smoke and pungent odor, leaving a charcoallish that retains the form of the original mass. When distilled in a retort it yields an empyreumatic oil, carburated hydrogen gas, carbonic acid, and a portion of ammonia, according to Fourcroy, the latter constituent being one of its elementary principles; and yet this ingredient does not appear in the result of the later analysis of Gay Lussac, and Thenard, which is, carbon, 22.33; oxygen, 41.78; hydrogen, 5.69; total 100.

692. Walnut. When wood is burnt in a smothered flame, the volatile parts are driven off by the heat, and there remains behind exhibiting the exact form, and even the several layers of the original mass. This process is denominated charring, and the substance obtained, charcoal. As it is the woody fibre alone which resists the action of heat, while the other parts of the plant are disintegrated, it is plausibly supposed that the woody fibre, and the quantity of resin insisted upon the quantity of the other, if they are not rather to be considered as the same. Charcoal may be obtained from almost all parts of the plant, whether solid or fluid. It often escapes, however, during combustion, under the form of carbonic acid, of which it constitutes a part. From the examination of charcoal, it appears that the green parts contain a greater proportion of charcoal than the roots. But this proportion is found to diminish in autumn, when the green parts begin to be deprived of their glutinous and extractive juice. The wood contains more charcoal than the alburnum, the bark more than both. But this last result is not constant in all plants, because the bark is not a homogeneous substance, the outer parts being affected by the air and the inner parts not. The wood of the quercus robur, separated from the alburnum, yielded 100 parts of its dried substance 1975 of charcoal; the alburnum, 75; the bark, 25; leaves gathered in May, 30; in September, 52. The charcoal of wood is very different in different parts of the world and in different seasons. The same charcoal is very different in different parts of the world and in different seasons. According to the experiments of Mushet, 100 parts of the following trees afforded as follows:—

692. The properties of charcoal are insolubility in water, of which however it absorbs a portion when newly heated, as also of atmospheric air. It is incapable of putrefaction. It is not altered by the most violent heat that can be applied, if burnt in the purest atmospheric air or oxygen gas, and if pure, without leaving any residuum. It is regarded by chemists as being a trichrome, of which the ingredients are carbon, hydrogen, and oxygen. Charcoal is of great utility both to the chemist and artist as a fuel for heating furnaces, as well as for a variety of other purposes, for purifying water, a very good tooth-powder; and is also an indispensable ingredient in the important manufacture of gunpowder.

693. The sap. If the branch of a vine is cut asunder early in the spring, before the leaves have begun to expand, a clear and colorless fluid will issue from the wound, which generally denominates the tree itself, but by no means is this the case as a result of the experiment. The sap, may be procured from almost any other plant by the same or similar means; but particularly from the maple, birch, and walnut-tree, by means of boring a hole in the trunk. It issues chiefly from the porous and mixed tubes of the
alburnum; though sometimes it does not flow freely till the bire is carried to the centre. A small branch of a vine has been known to yield from twelve to sixteen ounces, in the space of twenty-four hours. A similar occurrence was reported in a sapling in a season, as has been already stated; and a birch-tree has been known to yield in the course of the bleeding-season, 120 parts of the bark. Acidity equal to 10 per cent of acetic acid. In the sap of fagus sylvatica, Vaquelin found the following ingredients:—Water, acetic of lime, with excess of carbonate of potash, gallic acid, tannin, mucous and extractive matter, and aceta of alum. In 1603 parts of the bark he found 1027 parts of water, 208 parts of matter, $240 of acetate of potassic, 1,032 of vegetable matter, besides some slight indications of the presence of sulphuric and muriatic acids; and at a later period of the season he found the vegetable matter increased, and the carbonate of potassic diminished. From the above experiments, therefore, as well as from those of other chemists, it is plain that the sap consists of a great variety of ingredients, differing in different species of plants; though there is too little known concerning it to warrant the deduction of any general conclusions, as the number of plants whose sap has been hitherto analysed is yet but very limited. It is the grand source of vegetable extract, and may be regarded as being somewhat analogous to the blood of animals. It is not made use of by man, at least in its natural state. But there are trees, such as the birch, whose sap may be manufactured into a very pleasant wine; and it is well known that the maple-tree yields a considerable quantity of sugar.

701. The proper juice. When the sap has received its last degree of elaboration from the various parts or organs through which it has to pass, it is converted into a peculiar fluid, called the proper juice. This fluid may be distinguished from the sap by means of its color, which is generally green, as in periwinkle; or red, as in the linden; or blue, as in the sassafras. The most accurate experiments on the subject are those of Chapital. When oxymuriatic acid was poured into the peculiar juice of euphorbia, a very copious white precipitate fell down, which, when washed and dried, had the appearance of starch, or gelatin. Alcohol, added by the third, dissolved two thirds of it, which the addition of water again precipitated. They had all the properties of starch. The remaining third possessed the properties of woody fibre. The same experiment was tried on the juice of a variety of other plants, and the result uniformly was that oxymuriatic acid precipitated from them woody fibre.

702. The sources of their proper juice: and it seems indeed to be well founded. It is at least proved by experiment in the poppy, sarsaparilla, and fig. The juice of the first is narcotic, of the last corrosive. The diuretic and balsamic virtues of the fig reside in its turpentine, and the purgative property of jalap in its resin. If sugar is obtained from the sap of the sassafras and maple, it is only because it has been mixed with a quantity of proper juice. The bark contains in it a great abundance, as may be exemplified in cinnamon and quinquina. But the peach-tree furnishes an exception to this rule: its flowers are purgative, and the whole plant aromatic; but its gum is without any distinguished virtues. Malphigi regarded the proper juice as the principle of nourishment, and compared it to the blood of animals; but this analogy does not hold very closely. The sap is, perhaps, more analogous to the blood, from which the proper juice is rather a secretion. In one respect, however, the analogy holds good, that is, with regard to extravasated blood and peculiar juices in the plants, which seems neither derived from the latter, nor formed at the same time. The proper juices escape from the vessels containing them, they form neither wood nor bark, but a lump or deposit of precipitated fluid. To the sap or to the proper juice, or rather to a mixture of both, we must refer and assign the name of vitriol, because it is formed from the same substance, and they can come from no other source. In this state they are generally obtained in the first instance whether with a view to their use in medicine or their application to the arts. It is the business of the chemist or artist to separate and purify them afterwards according to the peculiar object he may have in view, and to use to which purposes to apply them. They contain, like the sap of vitriol, quantities of vitriol of lime, and assume a deeper shade of color when exposed to the fire or air. The oxymuriatic acid precipitates from them a colored and flaky substance as from the sap, and they yield by evaporation a quantity of extract. But they differ from the sap in exhibiting no traces of tannin or gallic acid, and but rarely of the sulphorific principle.

703. Ashes. When vegetables are burnt in the open air the greatest part of their substance is evaporated during the process of combustion; but ultimately there remains behind, a portion which is altogether insoluble, and which serves as the basis of the various substances of which the ashes of plants are composed. Herbaceous plants, after being dried, yield more ashes than woody plants; the leaves more than the branches; and the branches more than the trunk. The alburnum also yields more ashes than the wood, and putrefied vegetables yield more ashes than the same vegetables in a fresh state, if the putrefied vegetable is not taken placed in a current of water. The result of Sauussur's experiments on 160 parts of different plants was as follows:—

<table>

704. The analysis of the ashes of plants, with a view to the discovery of the ingredients of which they are composed, produces alkalies, earths, and metals, which must therefore be considered as ingredients in the composition of the vegetable. But vegetable ashes contain also a variety of other principles, occurring, however, in such small proportions as generally to escape observation. Perhaps they contain all substances not capable of being volatilized by the action of fire.
Alkalis. The alkalies are a peculiar class of substance, distinguished by a caustic taste and the property of changing vegetable substances into ashes. Ammonia, soda, and magnesia, of which the two former only are found in the ashes of vegetables. Ammonia is, indeed, often obtained from vegetable substances by means of distillation, but then it is always formed during the process. If the ashes of land vegetables, burnt in the open air, are repeatedly washed in water, and the residue of the potash is left in a crucible, the potash is precipitated in this manner, though it is not quite pure. But it may be purified by dissolving it in spirits of wine, and evaporating the solution to dryness in a silver vessel. When pure it is white and semi-transparent, and is extremely caustic and deliquescent. It dissolves, in a manner, chiefly in marine plants, from the ashes of which it is obtained by means of lixiviation. It exists in great abundance in sal soda, zosteria maritima, and in various species of fuci. It is generally obtained in the state of a carbonate, but is purified in the same manner as potash, for in this state it is similar in all its properties; but when purified, it is the silicate of alkali, and is obtained as a soft soap. It dissolves alkali silica, and also a small quantity of silex, with which it fuses into glass by the aid of fire. It had been long suspected by chemists to be a compound substance; and according to the notable discovery by Sir H. Davy, its component parts are at last ascertained to be a highly inflammable gas, or carbondioxide, and oxygen. The alkalis are composed of metallic species, generally of the alkali metals, or metals containing the same, but of all these the most abundant ingredient in the ashes of green herbaceous plants whose parts are in a state of vegetation. The ashes of the golden rod, growing in an uncultivated soil, and of the bean, turnsole, and wheat, were found by Saussure to contain at least three fourths of their weight of alkaline salts. This was nearly the case also with the leaves of the barley just emerging from the bud. But the proportion of alkaline salts is found to diminish rather than to augment as the parts of the plant are developed. The ashes of the leaves of the oak, gathered in May, yielded 47 parts in the 100, of alkaline salts; and in September, only 24.

The utility of the alkalies, as obtained from vegetables, is of the utmost importance in the arts, particularly in the formation of glass and of soaps. If a mixture of soda or potash, and silex or sand, in certain proportions, is exposed to a violent heat, the ingredients are melted down into a fluid mass, which is glass. In this state, however, it may be moulded into any form or shape, as a dish, vase, or tinted glass.

And accordingly we find that it is manufactured into a great variety of utensils and instruments, under the heads of dint-glass, crown-glass, bottle-glass. Bottle-glass is the coarsest; it is formed of soda and common sand, and is used in the manufacture of the coarser sort of bottles. Crown-glass is composed of soda and potash, and is used for the purpose of forming window-glasses and looking-glasses. Flint-glass is the finest and most transparent of all: that which is of the best quality is composed of 120 parts of white siliceous sand, 40 parts of pearl-ash, 55 of red oxide of lead, 13 of nitrate of potash, and 25 of black oxide of manganese, and is known also as plate-glass. It is known that when it is polished so as to serve for a variety of optical instruments, of which the discoveries of the telescope and the microscope are the curious or sublime results. If a quantity of oil is mixed with half its weight of a strong soot, and the combination is placed in a vessel which is rendered more complete by means of boiling, the new compound is soap. The union of oil with potash forms soft soap, and with soda hard soap; substances of the greatest efficacy as detergents, and of the greatest utility in the washing and bleaching of linen. The alkalies are used also in medicine, and are found to be peculiarly efficacious in the reduction of urine calculi.

Earths. The only earths which have hitherto been found in plants are the following: lime, silica, magnesia, alumina.

Of these earths, lime is by far the most abundant. It is generally combined with a portion of phosphoric acid, carbone, or sulphuric acid, forming phosphates, or carbonates, or sulphates of lime. The phosphate of lime is, next to the alkaline salt, the most abundant ingredient in the ashes of green herbaceous plants, whose parts are all in a state of vegetation. The leaf of a tree, bursting from the bud, contains in its ashes a greater proportion of earthy phosphate than at any other period; 100 parts of the ashes of the leaves of the oak, gathered in May, furnished 54 parts of earthy phosphate; in September, only 18-25. In annual plants the proportion of earthy phosphate diminishes from the period of their germination to that of their flowering. Plants of the bean, before flowering, gave 54 parts of earthy phosphates; at the time of flowering, only 18-25. In lichens the earthy phosphate of lime, the most abundant of the earthy salts that are found in vegetables. But if the leaves of plants are washed in water the proportion of carbonate is augmented. This is owing to the subtraction of their alkaline salts and phosphates in a greater proportion than their lime. In young herbaceous plants whose parts are in a state of vegetation, but the ashes of the barns of trees contain an enormous quantity of carbonate of lime, and much more than the abundance, as do also the ashes of the wood. The ashes of most seeds contain no carbonate of lime; but they abound in phosphate of potash. Hence the ashes of plants, at the period of the maturity of the fruit, yield less carbonate of lime than at any previous period.

Silica is not found to exist in a great proportion in the ashes of vegetables, unless they have been previously deprived of their salts and phosphates by washing; but when the plants are washed in water, the proportion of their silica augments. The ashes of the leaves of the rose, gathered in May, contained 23 parts of silica in 100. The same leaves, washed, yielded four parts in 100. Young plants, and leaves bursting from the bud, contain but little of silica in their ashes; but the proportion of silica augments as the parts are developed. But perhaps this is owing to the diminution of the alkaline salts. The ashes of some plants contain a time of a day or two after the blossom has withered, contained 12 parts of silica and 65 of alkaline salts in 100. At the period of their flowering, and when more of their leaves were withered, the ashes contained 32 parts of silica and 54 of alkaline salts. Seeds devided of their external covering, contain less silica than the stem furnished with its leaves. But the bark, the leaves, and wood, contain scarcely any silica, and the leaves a great deal, particularly in autumn. This is a phenomenon that seems inexplicable. The greater part of the grasses contain a very considerable proportion of silica, as do also the plants of the genus equisetum. Sir H. Davy has discovered that it forms a part of the epidermis of these plants, and in some few instances of the principal part. From 100 parts of the epidermis of the following plants the proportions of silica were, in bonnet cane, 90; bamboo, 71-4; common reed, 48-5; stalks of corn, 66-5. Owing to the silice in the contained in the epidermis, the plants in which it is found, are sometimes used to give a roughness to the surfaces to which it is applied. The Dutch cur' or equis' is made of Potentia, a plant of this kind, is used to polish even brass.

Magnesia does not exist so abundantly in the vegetable kingdom as the two preceding earths. It has been found, however, in several of the land plants, particularly the marine plants, not only in any other plant yet examined. According to Vauquelin, 100 parts of it contain 17,990 of magnesia.

Alumina has been detected in several plants, but never except in very small quantities.

Among the phenomena found in the ashes of vegetables, we must class also metals. They occur, however, only in small quantities, and are not to be detected except by the most delicate experiments. The metals hitherto discovered in plants are iron, manganese, and perhaps gold. Of these iron is by far the most common. It occurs in the state of an oxide, and the ashes of hard and woody plants, such as the oak, are said to contain nearly one twelfth of their own weight of this oxide. The ashes
of salsola contain also a considerable quantity. The oxide of manganese was first detected in the ashes of vegetables by Scheele, and afterwards found by Proust in the ashes of the pine, calendula, vine, green oak, and fig-tree. Beecher, Kunckel, and Sage, together with some other chemists, contend also for the existence of gold in the ashes of certain plants; but the very minute portion which they found, seems more likely to have proceeded from the lead employed in the process than from the ashes of the plant. It has been observed by Saussure, that the proportion of the oxides of iron and of manganese augments in the ashes of plants as their vegetation advances. The leaves of trees furnish more of these principles in autumn than in spring. It is so also with annual plants. Seeds contain metals in less abundance than the stem; and if plants are washed in water, the proportions of their metallic oxides is augmented.

712. Such are the principal ingredients that enter into the vegetable composition. They are indeed numerous, though some of them, such as the metallic oxides, occur in such small proportions as to render it doubtful whether they are in reality vegetable productions or no. The same thing may be said of the proportion of many of the other ingredients that have been found in the ashes of plants, which it is probable they have absorbed ready formed by the root, and deposited unaltered, so that they can scarcely be at all regarded as being the genuine products of vegetation.

713. Other substances. Besides the substances above enumerated, there are also several others that have been supposed to constitute distinct and peculiar genera of vegetable productions, and which might have been introduced under such a character; such as the mucous, jelly, sarcocell, asparagus, inulin, and alumin, of Dr. Thomson, as described in his well known System of Chemistry; but as there seems to be some difference of opinion among chemists with regard to them, and a belief entertained that they are but varieties of one or other of the foregoing ingredients, it is sufficient for the purposes of this work to have merely mentioned their names. Several other substances of a distinct and peculiar character have been suspected to exist in vegetable productions; such as the florescipe principle of Segin, as discovering itself in Peruvian bark; the principle of cautery or acidity of Seneuber, as discovering itself in the roots of ranunculus bulbous, scilla maritima, bryania alba, and arum maculatum, in the leaves of digitalis purpura, in the bark of daphne mezereum, and in the juice of the spurge; to which may be added the fluid secreted from the sting of the common nettle, the poisons inherent in some plants, and the medical virtues inherent in others; together with such peculiar principles as may be presumed to exist in such regions of the vegetable kingdom as remain yet unexplored. The important discoveries which have already resulted from the chemical analysis of vegetable substances encourage the hope that further discoveries will be the result of further experiment; and from the zeal and ability of such chemists as are now directing their attention to the subject, every thing is to be expected.

Sect. II. Simple Products.

714. From the above analysis of the vegetable subject, it is evident, that the compound ingredients of vegetables are all ultimately reducible to a few constituent and uncombined elements; and that the most essential of such compounds consist of carbon, oxygen, and hydrogen, merely; though others contain also a small proportion of nitrogen, said to be found only in cruciferae plants. The remaining elementary principles which plants have been found to contain, although they may be necessary in the vegetable economy, yet they are by no means principles of the first importance, as occurring only in small proportions, and being dependent in a great measure on soil and situation; whereas the elements of carbon, oxygen, and hydrogen, form as it were the very essence of the vegetable subject, and constitute by their modifications the peculiar character of the properties of the plant. This is conspicuously exemplified in the result of the investigations of Gay Lussac, and Thenard, who have deduced from a series of the most minute and delicate experiments the three following propositions, which they have dignified by the name of Laws of Vegetable Nature (Traite de Chem. Element. tom. iii. chap. iii.):-1st, Vegetable substances are always acid when the oxygen they contain is to the hydrogen in a greater proportion than in water; 2dly, Vegetable substances are always resinous, or oily, or spirituous, when the oxygen they contain is to the hydrogen in a smaller proportion than in water; 3dly, Vegetable substances are neither acid nor resinous, but saccharine or mucilaginous, or analogous to woody fibre or starch, when the oxygen and hydrogen they contain are in the same proportion as in water. Such is a brief sketch of the vegetable analysis: but if the reader, not being already an adept, wishes to descend into the detail of particulars and to prepare himself for original experiment, let him search out and peruse original papers, and let him consult the vegetable department of the several elementary publications referred to, especially that of Dr. Thomson's System of Chemistry; the most distinguished and elaborate of all our elementary works on the subject, and the guide chiefly applied to in the drawing up of the sketch that is here exhibited.

 chap. viii.

Functions of Vegetables.

715. From the analysis of the structure and principles of plants, the transition to their life, growth, and propagation is natural and easy. This subject necessarily involves the several following topics: germination; nutrition; digestion; growth and development of parts; anomalies of vegetable development; sexuality of vegetables; impregnation of the vegetable germs; changes consequent upon impregnation; propagation and dispersion of the species; causes limiting the dispersion of the species; evidence and character of vegetable vitality.
716. Germination is that act or operation of the vegetative principle by which the embryo is extricated from its envelopes, and converted into a plant. This is universally the first part of the process of vegetation. For it may be regarded as an indubitable fact, that all plants spring originally from seed. The conditions necessary to germination relate either to the internal state of the seed itself, or to the circumstances in which it is placed, with regard to surrounding substances.

717. The first condition necessary to germination is, that the seed must have reached maturity. Unripe seeds seldom germinate, because their parts are not yet prepared to form the chemical combinations on which germination depends. There are some seeds, however, whose germination is said to commence in the very seed-vessel, even before the fruit is ripe, and while it is yet attached to the parent plant. Such are those of the tan-gekolli of Adanson, and agave vivipara of East Florida, as well as of the cyamus nelumbo of Sir J. E. Smith, or sacred bean of India; to which may be added the seeds of the common garden-radish, pea, lemon, &c. But these are examples of rare occurrence; though it is sometimes necessary to sow or plant the seed almost as soon as it is fully ripe, as in the case of the coffee-bean; which will not germinate unless it is sown within five or six weeks after it has been gathered. But most seeds, if guarded from external injury, will retain their germinating faculty for a period of many years. This has been proved by the experiment of sowing seeds that have been long so kept; as well as by the deep ploughing up of fields that have been long left without cultivation. A field that was thus ploughed up near Dunkeld, in Scotland, after a period of forty years’ rest, yielded a considerable blade of black oats without sowing. It could have been only by the plough’s bringing up to the surface seeds that had been formerly too deeply lodged for germination.

718. The second condition is, that the seed sown must be defended from the action of the rays of light. This has no doubt been long known to be a necessary condition of germination, if we regard the practice of the harrowing or raking in of the grains or seeds sown by the farmer or gardener as being founded upon it.

719. A third condition necessary to germination is the access of heat. No seed has ever been known to germinate at or below the freezing point. Hence seeds do not germinate in winter, even though lodged in their proper soil. But the vital principle is not necessarily destroyed in consequence of this exposure; for the seed will germinate still, on the return of spring, when the ground has been again thawed, and the temperature raised to the proper degree. But this degree varies considerably in different species of seeds, as is obvious from observing the times of their germination, whether in the same or in different climates. For if seeds which naturally sow themselves, germinate in different climates at the same period, or in the same climate at different periods, the temperature necessary to their germination must of consequence be different. Now these cases are constantly occurring and presenting themselves to our notice; and have also been made the subject of particular observation. Adanson found that seeds which will germinate in the space of twelve hours in an ordinary degree of heat, may be made to germinate in the space of three hours by exposing them to a greater degree of heat; and that seeds transported from the climate of Paris to that of Senegal, have their periods of germination accelerated from one to three days. (Familles des Plantes, vol. i. p. 84.) Upon the same principle, seeds transported from a warmer to a colder climate, have their period of germination protracted till the temperature of the latter is raised to that of the former. This is well exemplified in the case of green-house and hot-house plants, from which it is also obvious that the temperature must not be raised beyond a certain degree, otherwise the vital principle is totally destroyed.

720. A fourth condition necessary to germination is the access of moisture. Seeds will not germinate if they are kept perfectly dry. Water, therefore, or some liquid equivalent to it, is essential to germination. Hence rain is always acceptable to the farmer or gardener, immediately after he has sown his seeds; and if no rain falls, recourse must be had, if possible, to artificial watering. But the quantity of water applied is not a matter of indifference. There may be too little, or there may be too much. If there is too little, the seed dies for want of moisture; if there is too much, it then rots. The case is not the same, however, with all seeds. Some can bear but little moisture, though others will germinate even when partially immersed; as was proved by an experiment of Du Hamel’s, at least in the case of pens, which he placed merely upon a piece of wet sponge, so as to immerse them by nearly the one half, and which germinated as if placed in the soil. But this was found to be the most they could bear; for when totally immersed in the water they rotted. There are some seeds, however, that will germinate even when wholly submersed. The seeds of aquatics must of necessity germinate under water; and peas have been also known to do so under certain conditions.

721. A fifth condition necessary to germination is the access of atmospheric air. Seeds will not germinate if placed in a vacuum. Ray introduced some grains of lettuce-seed
into the receiver of an air-pump, which he then exhausted. The seeds did not germinate. But they germinated upon the re-admission of the air, which is thus proved by consequence to be necessary to their germination. Achard proved that no seed will germinate in nitrogen gas, or carbonic acid gas, or hydrogen gas, except when mixed with a certain proportion of oxygen gas; and hence concluded that oxygen gas is necessary to the germination of all seeds, and the only constituent part of the atmospheric air which is absolutely necessary. Humboldt found that the process of germination is accelerated by means of previously steeping the seed in water impregnated with oxymuriatic acid. Cress-seed treated in this manner germinated in the space of three hours, though its ordinary period of germination is not less than thirty-two hours.

722. *The period necessary to complete the process of germination* is not the same in all seeds, even when all the necessary conditions have been furnished. Some species require a shorter, and others a longer period. The grasses are among the number of those plants whose seeds are of the most rapid germination; then perhaps cruciform plants; then leguminous plants; then labiate plants; then umbelliferous plants; and in the last order rosaceous plants, whose seeds germinate the slowest. The following table indicates the periods of the germination of a considerable variety of seeds, as observed by Adanson:

723. *Physical phenomena.* When a seed is committed to the soil under the conditions that have been just specified, the first invariable symptom of germination is to be deduced from the prolongation of the radicle (fig. 56. a), bursting through its proper integuments, and directing its extremity downwards into the soil. The next step in the process of germination is the evolution of the cotyledon or cotyledons (c), unless the seed is altogether acotyledonous, or the cotyledons hypogean, as in the oak (b). The next step, in the case of seeds furnished with cotyledons, is that of the extrication of the plumelet (e), or first real leaf, from within or from between the cotyledon or cotyledons, and its expansion in the open air. The last and concluding step is the development of the rudiments of a stem (d), if the species is furnished with a stem, and the plant is complete. Whatever way the seed may be deposited, the invincible tendency of the radicle is to descend and fix itself in the earth; and of the plumelet to ascend into the air. Many conjectures have been offered to account for this. Knight accounts for it on the old but revived principle of gravitation. Keith conjectures that it takes place from a power inherent in the vegetable subject, analogous to what we call instinct in the animal subject, infallibly directing it to the situation best suited to the acquisition of nutriment and consequent development of its parts.

724. *The chemical phenomena* of germination consist chiefly in the changes that are effected in the nutriment destined for the support and development of the embryo till it is converted into a plant. This nutriment either passes through the cotyledons, or is contained in them; because the embryo dies
when they are prematurely cut off. But the fluminaceous substance of the cotyledons, at least in exalbにおけるなき leafless seedlings, is a proof that they themselves contain the nutritious food. They are to be regarded, therefore, as an important part of the embryonic food of the plant. If the seed is furnished with a distinct and separate albumen, then is the albumen to be regarded as the repository of food, and the cotyledon or cotyledons as its channel of conveyance. But the food thus contained in the albumen or cotyledons is not yet fitted for the immediate nourishment of the embryo. Some previous preparation is necessary, and that change cannot be accomplished by the process of germination. And this change is effected by the intervention of chemical agency. The moisture imbibed by a seed placed in the earth is immediately absorbed by the cotyledons or albumen, which it readily penetrates, and on which it immediately begins to operate a chemical change, dissolving part of their food, and of forming a sort of emulsive juice. The consequence of this change is a slight degree of fermentation, induced, perhaps, by the mixture of the starch and gluten of the cotyledons in the water which they have absorbed, and indicated by the extraction of a quantity of carbonic acid gas as well as by the smell and taste of the seeds. This is the commencement of the process of germination, which takes place even though no oxygen gas is present. But if no oxygen gas is present, then the process stops; which shows that the agency of oxygen gas is indispensable to germination. Accordingly, when oxygen gas is present it is gradually inhaled by the seed; and the farina of the cotyledons is converted into sugar, carbonic acid, and oxygen, and an agency is indicated by the smell and taste of the radicle. The effect of oxygen, therefore, in the process, is that of converting the farina of the albumen or cotyledons into a mild and saccharine food, fit for the nourishment of the infant plant by diminishing the proportion of its carbon, and in augmenting, by consequence, that of its oxygen and hydrogen. The radicle gives the first indications of life, expanding and bursting its integuments, and at length fixing itself in the soil: the plumule next unfolds its parts, developing the rudiments of leaf, branch, and trunk; and, finally, the seminal leaves decay and drop off; and the embryo has been imparted into a plant, capable of abstracting immediately from the soil or atmosphere the nourishment necessary to its future growth.

Sect. II. Food of the Vegetating Plant.

725. The substances which plants abstract from the soil or atmosphere, or food of the vegetating plant, have long occupied the phytological enquirer. What then are the component principles of the soil and atmosphere? The investigations and discoveries of modern chemists have done much to elucidate this dark and intricate subject. Soil, in general, may be regarded as consisting of earths, water, vegetable mould, decayed animal substances, salts, ores, alkalies, gases, perhaps in a proportion corresponding to the order in which they are now enumerated; which is at any rate the fact with regard to the three first, though their relative proportions are by no means uniform. The atmosphere has been also found to consist of at least four species of elastic matter—nitrogen, oxygen, carbonic acid gas, and vapor; together with a multitude of minute particles detached from the solid bodies occupying the surface of the earth, and wafted upon the winds. The two former ingredients exist in the proportion of about four to one; carbonic acid gas in the proportion of about one part in 100; and vapor in a proportion still less. Such then are the component principles of the soil and atmosphere, and sources of vegetable nourishment. But the whole of the ingredients of the soil and atmosphere are not taken up indiscriminately by the plant and converted into vegetable food, because plants do not thrive indiscriminately in all varieties of soil. Part only of the ingredients are selected, and in certain proportions; as is evident from the analysis of the vegetable substance given in the foregoing chapter, in which it was found that carbon, hydrogen, oxygen, and nitrogen, are the principal ingredients of plants; while the other ingredients contained in them occur but in very small proportions. It does not however follow, that these ingredients enter the plant in an uncombined and insulated state, because they do not always so exist in the soil and atmosphere; it follows only that they are inhaled or absorbed by the vegetating plant under one modification or another. The plant then does not select such principles as are the most abundant in the soil and atmosphere; nor in the proportions in which they exist; nor in an uncombined and insulated state. But what are the substances actually selected; in what state are they taken up; and in what proportions? In order to give arrangement and elucidation to the subject, it shall be considered under the following heads: Water, Gases, Vegetable Extracts, Salts, Earths, Manures.
even when totally immersed, so as that no other food seems to have access to them; does it not follow that water is the sole food of plants, the soil being merely the basis on which they rest, and the receptacle of their food? This opinion has had many advocates; and the arguments and experiments adduced in support of it were, at one time, thought to have completely established its truth. It was indeed the prevailing opinion of the seventeenth century, and was embraced by several philosophers even of the eighteenth century; but its ablest and most zealous advocates were Van Helmont, Boyle, Du Hamel, and Bonnet, who contended that water, by virtue of the vital energy of the plant, was sufficient to form all the different substances contained in vegetables. Du Hamel reared in the above manner plants of the horse-chestnut and almond to some considerable size, and an oak till it was eight years old. And, though he informs us that they died at last only from neglect of watering: yet it seems extremely doubtful whether they would have continued to vegetate much longer, even if they had been watered ever so regularly; for he admits, in the first place, that they made less and less progress every year; and, in the second place, that their roots were found to be in a very bad state. The result of a great variety of experiments is, that water is not the sole food of plants, and is not convertible into the whole of the ingredients of the vegetable substance, even with the aid of the vital energy; though plants vegetating merely in water, do yet augment the quantity of their carbon.

727. **Gases.**

When it was found that water is insufficient to constitute the sole food of plants, recourse was next had to the assistance of the atmospheric air; and it was believed that the vital energy of the plant is at least capable of furnishing all the different ingredients of the vegetable substance, by means of decomposing and combining, in different ways, atmospheric air and water. But as this extravagant conjecture is founded on no proof, it is consequently of no value. It must be confessed, however, that atmospheric air is indispensably necessary to the health and vigor of the plant, as may be seen by looking at the different aspects of plants exposed to a free circulation of air, and plants deprived of it: the former are vigorous and luxuriant; the latter weak and stunted. It may be seen also by means of experiment even upon a small scale. If a plant is placed under a glass to which no new supply of air has access, it soon begins to languish, and at length withers and dies; but particularly if it is placed under the exhausted receiver of an air-pump; as might indeed be expected from the failure of the germination of the seed in similar circumstances. The result of experiments on this subject is, that atmospheric air and water are not the only principles constituting the food of plants. But as in germination, so also in the progress of vegetation, it is partly from the component principles of the atmospheric air that are adapted to the purposes of vegetable nutrition, and selected by the plant as a food. Let us take them in the order of their reversed proportions.

728. **The effect of the application of carbonic acid gas was found to be altogether prejudicial in the process of the germination of the seed.** But in the process of subsequent vegetation its application has been found, on the contrary, to be extraneously induced vegetable. Plants were not induced vegetate in an atmosphere of pure carbonic acid, as was first ascertained by Dr. Priestley, who found that sprigs of mint growing in water, and placed over put in an atmosphere of carbonic acid, generally became quite dead in the space of a day, and did not even recover when put into an atmosphere of common air. Of a number of experiments the result was, that the application of carbonic acid to the leaves and branches of plants, as applied to the leaves and branches; and whatever increases the proportion of this gas in their atmosphere, at least within a given degree, forwards vegetation; 2d. That, as applied to the leaves and branches of plants, it is prejudicial to their vegetation in the shade, if administered in a proportion beyond that in which it exists in atmospheric air; 3d. That carbonic acid gas, as applied to the roots of plants, is also beneficial to their growth, at least in the more advanced stages of vegetation.

729. **As oxygen is essential to the commencement and progress of germination, so also it is essential to the progress of vegetation.** It is obvious, then, that the experiment proves that it is beneficial to the growth of the vegetable as applied to the root; necessary to the development of the leaves; and to the development of the flower and fruit. The flower-bud will not expand if confined in an atmosphere deprived of oxygen, nor will the fruit ripen. Flower-buds confined in an atmosphere of pure carbonic acid, remains unopened. A bunch of grape grapes introduced into a globe of glass, which was hermetically closed by its orifice to the bough, and exposed to the sun, ripened without affecting any material alteration in its atmosphere. But when a bunch was placed in the same circumstances, with the addition of a quantity of lime-water the grapes did not ripen. The oxygen, therefore, is essential to the development of the vegetating plant, and is inhaled during the night.

730. **Though nitrogene gas constitutes by far the greater part of the mass of atmospheric air, it does not seem capable of furnishing nourishment to plants; for as seeds will not germinate, so neither will plants vegetate in it, but for a very limited time, such as the vinca minor, lythrum salicaria, inula discentera, euphobia hirsutum, and polygonum persicaria, that seem to succeed equally well in an atmosphere of nitrogene gas as in an atmosphere of common air.** Nitrogen is found in almost all vegetables, particularly in the wood, in extract, and in their green parts, derived, no doubt, from the extractive principle of vegetable food.

731. **Hydrogen gas.** A plant of the epilobium hirsutum, which was confined by Priestley in a receiver filled with inflammable air or hydrogen, consumed one third of its atmosphere and was still green. Here we have vegetable food, yet it produces a living plant and not a dead flabulum of the plant. But the experiments of later physiologists do not at all countenance this opinion. Our conclusion from various experiments is, that hydrogen is unfavorable to vegetation, and does not serve as the food of plants. But hydrogen is evidently present in plants, and if it does not serve as the food of plants, how is it possible to account for it? This question it is sufficient for the present to reply, that if plants do not acquire their hydrogen in the state of gas, they may at least acquire it in the state of water, which is indisputably a vegetable food, and of which hydrogen constitutes one of the component parts.
732. Vegetable Extract. When it was found that atmospheric air and water are not, even conjointly, capable of furnishing the whole of the aliment necessary to the development of the plant, it was then alleged that, with the exception of water, all substances constituting a vegetable food must at least be administered to the plant in a gaseous state. But this also is a conjecture unsupported by proof; for even with regard to such plants as grow upon a barren rock, or in pure sand, it cannot be said that they receive no nourishment whatever besides water, except in a gaseous state. Many of the particles of decayed animal and vegetable substances, which float in the atmosphere and attach themselves to the leaves, must be supposed to enter the plant in solution with the moisture which the leaves imbibe; and so also similar substances contained in the soil must be supposed to enter it by the root: but these substances may certainly contain vegetable nourishment; and they will perhaps be found to be taken up by the plant in proportion to their degree of solubility in water, and to the quantity in which they exist in the soil. Now one of the most important of these substances is vegetable extract. When plants have attained to the maturity of their species, the principles of decay begin gradually to operate upon them, till they at length die and are converted into dust or vegetable mould, which, as might be expected, constitutes a considerable proportion of the soil. The chance then is, that it is again converted into vegetable nourishment, and again enters the plant. But it cannot wholly enter the plant, because it is not wholly soluble in water. Part of it, however, is soluble, and consequently capable of being absorbed by the root, and that is the substance which has been denominated extract. Saussure filled a large vessel with pure mould of turf, and moistened it with distilled or rain water, till it was saturated. At the end of five days, when it was subjected to the action of the press, 10,000 parts in weight of the expressed and filtered fluid yielded, by evaporation to dryness, 26 parts of extract. In a similar experiment upon the mould of a kitchen-garden which had been manured with dung, 10,000 parts of fluid yielded 10 of extract. And in a similar experiment upon mould taken from a well cultivated corn-field, 10,000 parts of fluid yielded four parts of extract. Such was the result in these particular cases. But the quantity of extract that may be separated from common soil is not in general very considerable. After twelve decoctions, all that could be separated was about one eleventh of its weight; and yet this seems to be more than sufficient for the purposes of vegetation: for a soil containing this quantity was found by experiment to be less fertile, at least for peas and beans, than a soil that contained only one half or two thirds the quantity. But if the quantity of extract must not be too much, neither must it be too little. Plants that were put to vegetate in soil deprived of its extract, as far as repeated decoctions could deprive it, were found to be much less vigorous and luxuriant than plants vegetating in soil not deprived of its extract; and yet the only perceptible difference between them is, that the former can imbibe and retain a much greater quantity of water than the latter. From this last experiment, as well as from the great proportion in which it exists in the living plant, it evidently follows that extract constitutes a vegetable food. But extract contains nitrogen; for it yields by distillation a fluid impregnated with ammonia. The difficulty, therefore, of accounting for the introduction of nitrogen into the vegetating plant, as well as for its existence in the mature vegetable substance, is done away; for, although the plant refuses it when presented in a gaseous state, it is plain that it must admit it along with the extract. It seems also probable that a small quantity of carbonic acid gas enters the plant along with the extractive principle, as it is known to contain this gas also.

733. Salts, in a certain proportion, are found in most plants, such as nitrate, muriate, and sulphate of potash or soda, as has been already shown. These salts are known to exist in the soil, and the root is supposed to absorb them in solution with the water by which the plant is nourished. It is at least certain that plants may be made to take up by the roots a considerable proportion of salts in a state of artificial solution. But if salts are thus taken up by the root of the vegetating plant, does it appear that they are taken up as a food? Some plants, it must be confessed, are injured by the application of salts, as is evident from the experiments of Saussure; but others are as evidently benefited by it. Trefoil and lucerne have their growth much accelerated by the application of sulphate of lime, though many other plants are not at all influenced by its action. The parietaria, nettle, and borage will not thrive, except in such soils as contain nitrate of lime or nitrate of potash; and plants inhabiting the sea-coast, as was observed by Du Hamel, will not thrive in a soil that does not contain muriate of soda. It has been thought, however, that the salts are not actually taken up by the root, though converted to purposes of utility by acting as astringents or corrosives in stopping up the orifices of the vessels of the plant, and preventing the admission of too much water: but it is to be recollected that the salts in question are found by analysis in the very substance of the plant, and must consequently have entered in solution. It has been also thought that salts are favorable to vegetation only in proportion as they hasten the putrefaction of vegetable substances contained in the soil, or attract the humidity of the atmosphere. But sulphate of lime is
not deliquescent; and if its action consist merely in accelerating putrefaction, why is its beneficial effect confined but to a small number of plants? Grisenthwaite (New Theory of Agriculture, 1819, p. 111.) answers this question by stating, that as in the principal grain-crops which interest the agriculturist, there exists a particular saline substance, peculiar to each, so, if we turn our attention to the clovers, and turnips, we shall still find the same discrimination. Saintfoin, clover, and lucerne, have long been known to contain a notable quantity of gypsum (sulphate of lime); but such knowledge, very strange to relate, never led to the adoption of gypsum as a manure for those crops, any more than that of phosphate of lime for wheat, or nitrate of soda, or potassa for barley. It is true that gypsum has been long, and in various places, recommended as a manure, but its uses not being understood, it was recommended without any reference to crop, or indeed to the accomplishment of any fixed object. It is very well known that some particular ingredient may be essential to the composition of a body, and yet constitute but a very small proportion of its mass. Atmospheric air contains only about one part in the 100 of carbonic acid; and yet no one will venture to affirm that carbonic acid gas is merely an adventitious and accidental element existing by chance in the air of the atmosphere, and not an essential ingredient in its composition. Phosphate of lime constitutes but a very small proportion of animal bodies, perhaps not one part in 500; and yet no one doubts that it is essential to the composition of the bones. But the same salt is found in the ashes of all vegetables; and who will say that is not essential to their perfection?

734. Earths. As most plants have been found by analysis to contain a portion of alkaline or earthy salts, so most plants have been found to contain also a portion of earths: and as the two substances are so nearly related, and so foreign in their character to vegetable substances in general, the same enquiry has consequently been made with regard to their origin. Whence are the earths derived that have been found to exist in plants? Chiefly from the soil. But in what peculiar state of combination do they enter the vessels of the plant? The state most likely to facilitate their absorption is that of their solution in water, in which all the earths hitherto found in plants are known to be in a slight degree soluble. If it be said that the proportion in which they are soluble is so very small that it scarcely deserves to be taken into the account, it is to be recollected that the quantity of water absorbed by the plant is great, while that of the earth necessary to its health is but little, so that it may easily be acquired in the progress of vegetation. Such is the manner in which their absorption seems practicable: and Woodward’s experiments afford a presumption that they are actually absorbed by the root. The proportion of earths contained in the ashes of vegetables depends upon the nature of the soil in which they grow. The ashes of the leaves of the rhododendron ferrugineum, growing on Mount Jura, a calcareous mountain, yielded 43-25 parts of earthy carbonate, and only 0-75 of silica. But the ashes of leaves of the same plant, growing on Mount Breen, a granitic mountain, yielded two parts of silica, and only 16-75 of earthy carbonate. It is probable, however, that plants are not indebted merely to the soil for the earthy particles which they may contain. They may acquire them partly from the atmosphere. Margin has shown that rain-water contains silica in the proportion of a grain to a pound; which, if it should not reach the root, may possibly be absorbed along with the water that adheres to the leaves. But although the earths are thus to be regarded as constituting a small proportion of vegetable food, they are not of themselves sufficient to support the plant, even with the assistance of water. Gibert mixed together lime, alumine, silica, and magnesia, in such proportions as are generally to be met with in fertile soils, and moistened them with water. Several different grains were then sown in this artificial soil, which germinated indeed, but did not thrive; and perished when the nourishment of the cotyledons was exhausted. It is plain, therefore, that the earths, though beneficial to the growth of some vegetables, and perhaps necessary to the health of others, are by no means capable of affording any considerable degree of nourishment to the plant.

735. Supply of food by manures and culture. With regard to the food of plants derived from the atmosphere, the supply is pretty regular, at least, in as far as the gases are concerned; for they are not found to vary materially in their proportions on any part of the surface of the globe: but the quantity of moisture contained in the atmosphere is continually varying, so that in the same season you have not always the same quantity, though in the course of the year the deficiency is perhaps made up. From the atmosphere, therefore, there is a regular supply of vegetable food kept up by nature for the support of vegetable life, independent of the aid of man: and if human aid were even wanted, it does not appear that it could be of much avail. But this is by no means the case with regard to soils; for if soils are less regular in their composition, they are at least more within the reach of human management. The supply of food may be increased by altering the mechanical or chemical constitution of soils; and by the addition of food in the form of manures. The mechanical constitution of soils may be altered by pulverisation, consolidation, draining, and watering; their chemical properties by aeration and torification; both mechanical and chemical properties, by the addition of earths or other sub-
stances; and manures, either liquid or solid, are supplied by irrigation and distribution of dung and other nourishing matters, with or without their interment. (See Book II.)

736. Soils in a state of culture, though consisting originally of the due proportion of ingredients, may yet become exhausted of the principle of fertility by means of too frequent cropping; whether by repetition or rotation of the same, or of different crops. In this case, it should be the object of the phytologist, as well as of the practical cultivator, to ascertain by what means fertility is to be restored to an exhausted soil, or communicated to a new one. In the breaking up of new soils, if the ground has been wet or marshy, as is frequently the case, it is often sufficient to prepare it merely by means of draining off the superfluous and stagnant water, and of paring and burning the turf upon the surface. If the soil has been exhausted by too frequent a repetition of the same crop, it often happens that a change of crop will answer the purpose of the cultivator; for although a soil may be exhausted for one sort of grain, it does not necessarily follow that it is also exhausted for another. And accordingly, the practice of the farmer is to sow his crops in rotation, having in the same field a crop, perhaps, of wheat, barley, beans, and tares in succession; each species selecting in its turn some peculiar nutrient, or requiring, perhaps, a smaller supply than the crop that has preceded it. But even upon the plan of rotation, the soil becomes at length exhausted, and the cultivator obliged to have recourse to other means of restoring its fertility. In this case, an interval of repose is considerably efficacious, as may be seen from the increased fertility of fields that have not been ploughed up for many years, such as those used for pasture; or even from that the walks and paths in gardens when they are again broken up. Hence also the practice of fallowing, and of trenching or deep ploughing, which in some cases has nearly the same effect.

737. The fertility of a soil is restored, in the case of draining, by means of its carrying off all such superfluous moisture as may be lodged in the soil, which is well known to be prejudicial to plants not naturally aquatics, as well as by rendering the soil more firm and compact. In the case of burning, the amelioration is effected by means of the decomposition of the vegetable substances contained in the turf, and subjected to the action of the fire, which disperses part also of the superfluous moisture, but leaves a residue of ashes favorable to future vegetation. In the case of the rotation of crops, the fertility is not so much restored as more completely developed and brought into action; because the soil, though exhausted for one species of grain, is yet found to be sufficiently fertile for another, the food necessary to each being different, or required in less abundance. In the case of the repose of the soil, the restored fertility may be owing to the decay of vegetable substances that are not now carried off in the annual crop, but left to augment the proportion of vegetable mould; or to the accumulation of fertilising particles conveyed to the soil by rains; or to the continued abstraction of oxygen from the atmosphere. In the case of falls, it is owing undoubtedly to the action of the atmospheric air upon the soil, whether in rendering it more friable, or in hastening the putrefaction of noxious plants; or it is owing to the abstraction and accumulation of oxygen. In the case of trenching, or deep ploughing, it is owing to the increased facility with which the roots can now penetrate to the proper depth, and thus their sphere of nourishment is increased. But it often happens that the soil can no longer be ameliorated by any of the foregoing means, or not at least with sufficient rapidity for the purposes of the cultivator; and in this case there must be a direct and actual application made to it of such substances as are fitted to restore its fertility. Hence the indispensable necessity of manures, which consist chiefly of animal and vegetable remains that are buried and finally decomposed in the soil, from which they are afterwards absorbed by the root of the plant, in a state of solution.

738. But as carbon is the principal ingredient furnished by manures, as contributing to the nourishment of the plant, and is not itself soluble in water, nor even disengaged by fermentation in a state of purity; under what state of chemical combination is its solution effected? Is it effected in the state of charcoal? It has been thought, indeed, that carbon in the state of charcoal is soluble in water; because water from a dunghill, when evaporated, constantly leaves a residuum of charcoal, as was first ascertained by the experiments of Hassenfratz. But there seem to be reasons for doubting the legitimacy of the conclusion that has been drawn from it; for Senebier found that plants whose roots were immersed in water took up less of the fluid in proportion as it was mixed with water from a dunghill. Perhaps then the charcoal of water from a dunghill is held merely in suspension, and enters the plant under some other modification. But if carbon is not soluble in water in the state of charcoal, in what other state is it soluble? It is soluble in the state of carbonic acid gas. But is this the state in which it actually enters the root? On this subject phytologists have been somewhat divided in opinion. Senebier endeavour to prove that carbonic acid gas, dissolved in water, supplies the roots of plants with almost all their carbon, and founds his arguments upon the following facts: — in the
first place, it is known that carbonic acid gas is soluble in water; in the second place, it is known to be contained in the soil, and generated by the fermentation of the materials composing manures; and, in the next place, it is known to be beneficial to vegetation when applied artificially to the roots, at least in a certain degree. This is evident from the following experiment of Ruckert, as well as from several experiments of Saussure’s, previously related. Ruckert planted two beans in pots of equal dimensions, filled with garden-mould; the one was moistened with distilled water, and the other with water impregnated with carbonic acid gas. But the latter appeared above ground nine days sooner than the former, and produced twenty-five beans; while the former produced only fifteen. Now the result of this experiment, as well as the preceding facts, is evidently favorable to the presumption of Senebier, and shows that if carbonic acid is not the state in which carbon enters the plant, it is at least a state preparatory to it; and there are other circumstances tending to corroborate the opinion, resulting from the analysis of the ascending sap of plants. The tears of the vine, when analysed by Senebier, yielded a portion of carbonic acid and earth; and as the ascending sap could not be supposed to have yet undergone much alteration, the carbonic acid, like the earth, was probably taken up from the soil. But this opinion, which seems to be so firmly established upon the basis of experiment, Hassenfratz strenuously controverts. According to experiments which he had instituted with an express view to the investigation of this subject, plants which were raised in water impregnated with carbonic acid differed in no respect from such as grew in pure water, and contained no carbon that did not previously exist in the seed. Now if this were the fact, it would be decisive of the point in question. But it is plain from the experiments of Saussure, as related in the preceding section, that Hassenfratz must have been mistaken both with regard to the utility of carbonic acid gas as furnishing a vegetable aliment, and with regard to the augmentation of carbon in the plant. The opinion of Senebier, therefore, may still be correct. It must be acknowledged, however, that the subject is not yet altogether satisfactorily cleared up; and that carbon may certainly enter the plant in some state different from that, either of charcoal in solution, or of carbonic acid gas. Is not the carbonic acid of the soil decomposed before entering the plant? This is a conjecture of Dr. Thomson’s, founded upon the following facts: — the green oxide of iron is capable of decomposing carbonic acid; and many soils contain that oxide. Most soils, indeed, contain iron, either in the state of the brown or green oxides, and it has been found that oils convert the brown oxide into green. But dung and rich soils contain a quantity of oily substance. One effect of manures, therefore, may be that of reducing the brown oxide of iron to the green, thus rendering it capable of decomposing carbonic acid gas, so as to prepare it for some new combination, in which it may serve as an aliment for plants. All this, however, is but a conjecture; and it is more probable that the carbonic acid of the soil enters the root in combination with some other substance, and is afterwards decomposed within the plant itself.

**Sect. III. Process of Vegetable Nutrition.**

739. **Plants are nourished in a manner in some degree analogous to the animal economy.** The food of plants, whether lodged in the soil, or wafted through the atmosphere, is taken up by intro-susception in the form of gases or other fluids: it is then known as their sap; this sap ascends to the leaves, where it is elaborated as the blood of animals is in the lungs; it then enters into the general circulation of the plant, and promotes its growth.

740. **Intro-susception.** As plants have no organ analogous to the mouth of animals, they are enabled to take up the nourishment necessary to their support only by absorption, or inhalation as the chyle into the animal lacteals, or the air into the lungs. The former term is applied to the intro-susception of non-elastic fluids; the latter to that of gaseous fluids. The absorption of non-elastic fluids by the epidermis of plants does not admit of a doubt. It is proved, indisputably, that the leaves not only contain air, but do actually inhale it. It was the opinion of Priestley that they inhale it chiefly by the upper surface. And it has been shown by Saussure, that their inhaling power depends entirely upon the organisation. It has been a question, however, among phytologists, whether it is not also effected by the epidermis of the other parts of the plant. We can scarcely suppose it to be effected by the dry and indurated epidermis of the bark of aged trunks, of which the original organisation is obliterated; nor by that of the larger and more aged branches. But it has been thought there are even some of the soft and succulent parts of the plant by which it cannot be effected, because no pores are visible in their epidermis. Decandolle found no pores in the epidermis of fleshy fruits, such as pears, peaches, and gooseberries; nor in that of roots, or scales of bulbs; nor in any part not exposed to the influence of air and light. It is known, however, that fruits will not ripen, and that roots will not thrive, if wholly deprived of air; and hence it is probable that they inhale it by their epidermis, though the pores by which it enters should not be visible. In the root, indeed, it may possibly enter in combination with the moisture of the soil; but in the other parts of the plant it enters no doubt in the state of gas. Herbs, therefore, and the
soft parts of woody plants, absorb moisture and inhale gases from the soil or atmosphere by means of the pores of their epidermis, and thus the plant effects the intro-susception of its food.

741. Ascent of the sap. The means by which the plant effects the intro-susception of its food, is chiefly that of absorption by the root. But the fluids existing in the soil when absorbed by the root, are designated by the appellation of sap or lymph; which, before it can be rendered subservient to the purposes of vegetable nutrition, must either be immediately conveyed to some viscous proper to give it elaboration, or immediately distributed throughout the whole body of the plant. Our present object, therefore, is that of tracing out the progress of its distribution or ascent. The sap is in motion in one direction or other, if not all the year, at least at occasional periods, as the bleeding of plants in spring and autumn sufficiently illustrates. The plant always bleeds most freely about the time of the opening of the bud; for in proportion as the leaves expand, the sap flows less copiously, and when they are fully expanded, it entirely ceases. But this suspension is only temporary, for the plant may be made to bleed again in the end of the autumn, at least under certain conditions. If an incision is now made into the body of the tree, after the occurrence of a short but sharp frost, when the heat of the sun or mildness of the air begins to produce a thaw, the sap will again flow. It will flow even where the tree has been but partially thawed, which sometimes happens on the south side of a tree, when the heat of the sun is strong and the wind northerly. At the seasons now specified, therefore, the sap is evidently in motion; but the plant will not bleed at any other season of the year. It has been the opinion of some phytologists, that the motion of the sap is wholly suspended during the winter. But though the great cold of winter, as well as the great heat of summer, is by no means so favorable to vegetation as the milder though more changeable temperature of spring and autumn, yet it does not wholly suspend the movement of the sap. Palms may be made to bleed at any season of the year. And although this is not the case with plants in general, yet there is proof sufficient that the colds of winter do not, even in this climate, entirely prevent the sap from flowing. Buds exhibit a gradual development of parts throughout the whole of the winter, as may be seen by dissecting them at different periods. So also do roots. Evergreens retain their leaves; and many of them, such as the arbutus, laurustinus, and the beautiful tribe of the mosses, protrude also their blossoms, even in spite of the rigor of the season. But all this could not possibly be accomplished, if the motion of the sap were wholly suspended.

742. Thus the sap is in perpetual motion with a more accelerated or more diminished velocity throughout the whole of the year; but still there is no decided indication, exhibited in the mere circumstance of the plant's bleeding, of the direction in which the sap is moving at the time; for the result might be the same whether it was passing from the root to the branches, or from the branches to the root. But as the great influx of the sap is effected by means of the pores of the epidermis of the root, it follows that its motion must, at least in the first place, be that of ascent; and such is its direction at the season of the plant's bleeding, as may be proved by the following experiment: — if the bore or incision that has been made in the trunk is minutely inspected while the plant yet bleeds, the sap will be found to issue almost wholly from the inferior side. If several bores are made in the same trunk, one above another, the sap will begin to flow first from the lower bore, and then from those above it. If a branch of a vine be lopped, the sap will issue copiously from the section terminating the part that remains yet attached to the plant; but not from the section terminating the part that has been lopped off. This proves indubitably that the direction of the sap's motion, during the season of the plant's bleeding, is that of ascent. But if the sap flows so copiously during the season of bleeding, it follows that it must ascend with a very considerable force; which force has accordingly been made the subject of calculation. To the stem of a vine cut off about two feet and a half from the ground, Hales fixed a mercurial gauge which he luted with mastic; the gauge was in the form of a syphon, so contrived that the mercury might be made to rise in proportion to the pressure of the ascending sap. The mercury rose accordingly, and reached, as its maximum, to a height of thirty-eight inches. But this was equivalent to a column of water of the height of forty-three feet three and one-third inches; demonstrating a force in the motion of the sap that, without the evidence of experiment, would have seemed altogether incredible.

743. Thus the sap in ascending from the lower to the upper extremity of the plant is propelled with a very considerable force, at least in the bleeding season. But is the ascending sap propelled indiscriminately throughout the whole of the tubular apparatus, or is it confined in its course, to any particular channel? Before the anatomy of plants had been studied with much accuracy, there was a considerable diversity of opinion on the subject. Some thought it ascended by the bark; others thought it ascended by the bark, wood, and pith indiscriminately; and others thought it ascended between the bark and wood. The first opinion was maintained and supported by Malpighi; and Grew considers that the
sap ascends by the bark, wood, and pith, indiscriminately. Du Hamel strip\* several trees of their bark entirely, which continued, notwithstanding, to live for many years, protruding new leaves and new branches as before. Knight strips the trunk of a number of young crab-trees of a ring of bark half an inch in breadth, but the leaves were protruded, and the branches elongated, as if the operation had not been performed. Du Petit Thouars removed the central wood and pith from the stems of several young sycamore trees, leaving the upper part to be supported only by four pillars of bark: in others he removed the bark, liber, and alburnum, leaving the upper part of the tree to be supported solely by the central wood. In both cases the trees lived, so that he concludes the bark and wood can alternately act as the sap's conductor. (Hist. d'un Morceau de Bois. Hort. Tourr. 481.)

744. It is evident, therefore, that the sap does not ascend exclusively by the bark. But it is equally evident that it does not ascend by the pith, at least after the first year; for then, even upon Grew's own supposition, it becomes either juiceless or wholly extinct: and even during the first year it is not absolutely necessary, if at all subservient to the ascent of the sap, as is proved by an experiment of Knight's. Having contrived to abstract from some annual shoots a portion of their pith, so as to interrupt its continuity, but not otherwise materially to injure the fabric of the shoot, Knight found that the growth of the shoots which had been made the subject of experiment was not at all affected by it.

745. Thus the sap ascends neither by the bark nor pith, but by the wood only. But the whole mass of the wood throughout is not equally well adapted for the purpose of conveying it. The interior and central part, or that part that has acquired its last degree of solidity, does not in general afford it a passage. This is proved by what is called the girdling of trees, which consists in making a circular gap or incision quite round the stem, and to the depth of two or three inches, so as to cut through both the bark and alburnum. An oak-tree on which Knight had performed this operation, with a view to ascertaining the channel of the sap's ascent, exhibited not the slightest mark of vegetation in the spring following. The sap then does not ascend through the channel of the matured wood. But if the sap ascends neither through the channel of the bark, nor pith, nor matured wood, through what other channel does it actually ascend? The only remaining channel through which it can possibly ascend is that of the alburnum. In passing through the channel of the alburnum, does the sap ascend promiscuously by the whole of the tubes composing it, or is it confined in its passage to any peculiar set? The earliest conjectures recorded on this subject are those of Grew and Malpighi, who, though they maintained that the sap ascends chiefly by the bark, did not yet deny that it ascends also partly by the alburnum or wood. It occurred to succeeding physiologists that the progress of the sap, and the vessels through which it passes, might be traced or ascertained by means of making plants vegetate in colored infusions. Du Hamel steeped the extremities of branches of the fig, elder, honeysuckle, and filbert in common ink. In examining the two former, after being steeped for several days, the part immersed was found to be black throughout, but the upper part was tinged only in the wood, which was colored for the length of a foot, but more faintly and partially in proportion to the height. The pith, indeed, exhibited some traces of ink, but the bark and buds none. In some other examples the external layers of the wood only were tinged. In the honeysuckle the deepest shade was about the middle of the woody layers; and in the filbert there was also observed a colored circle surrounding the pith, but none in the pith itself, nor in the bark.

746. Thus it is proved that the sap ascends through the vessels of the longitudinal fibre composing the alburnum of woody plants, and through the vessels of the several bundles of longitudinal fibre constituting the woody part of herbaceous plants. But it has been already shown that the vessels composing the woody fibre are not all of the same species. There are simple tubes, porous tubes, spiral tubes, mixed tubes, and interrupted tubes. Through which of these, therefore, does the sap pass in its ascent? The best reply to this enquiry has been furnished by Knight and Mirbel. Knight prepared some annual shoots of the apple and horse-chestnut, by means of circular incisions, so as to leave detached rings of bark with insulated leaves remaining on the stem. He then placed them in colored infusions obtained by macerating the skins of very black grapes in water; and, on examining the transverse section at the end of the experiment, it was found that the infusion had ascended by the wood beyond his incisions, and also into the insulated leaves, but had not colored the pith nor bark, nor the sap between the bark and wood. From the above experiment, Knight concludes that the sap ascends through what are called the common tubes of the wood and alburnum, at least till it reaches the leaves. Thus the sap is conveyed to the summit of the alburnum. But Knight's next object was to trace the vessels by which it is conveyed into the leaf. The apple-tree and horse-chestnut were still his subjects of experiment. In the former the leaves are attached to the plant by three strong fibres, or rather bundles of tubes, one in the middle of the leaf-stalk, and one on each side. In the latter they are attached by means of several
such bundles. Now the colored fluid was found in each case to have passed through the centre of the several bundles, and through the centre only, tingeing the tubes throughout almost the whole length of the leaf-stalk. In tracing their direction from the leaf-stalk upwards, they were found to extend to the extremity of the leaves; and in tracing their direction from the leaf-stalk downwards, they were found to penetrate the bark and alburnum, the tubes of which they join, descending obliquely till they reach the pith which they surround. From their position Knight calls them central tubes, thus distinguishing them from the common tubes of the wood and alburnum, and from the spiral tubes with which they were everywhere accompanied as appendages, as well as from a set of other tubes which surrounded them, but were not colored, and which he designates by the appellation of external tubes. The experiment was now transferred to the flower-stalk and fruit-stalk, which was done by placing branches of the apple, pear, and vine, furnished with flowers not yet expanded, in a decoction of logwood. The central vessels were rendered apparent as in the leaf-stalk. When the fruit of the two former was fully formed, the experiment was then made upon the fruit-stalk, in which the central vessels were sought as before; but the coloring matter was found to have penetrated into the fruit also, diverging round the core, approaching again in the eye of the fruit, and terminating at last in the stamens. It was by means of a prolongation of the central vessels, which did not however appear to be accompanied by the spiral tubes beyond the fruit-stalk. Such then are the parts of the plant through which the sap ascends, and the vessels by which it is conveyed. Entering by the pores of the epidermis, it is received into the longitudinal vessels of the root by which it is conducted to the collar. Thence it is conveyed by the longitudinal vessels of the alburnum, to the base of the leaf-stalk and peduncle; from which it is further transmitted to the extremity of the leaves, flower, and fruit. There remains a question to be asked intimately connected with the sap's ascent. Do the vessels conducting the sap communicate with one another by inosculation or otherwise, so as that a portion of their contents may be conveyed in a lateral direction, and consequently to any part of the plant; or do they form distinct channels throughout the whole of their extent, having no sort of communication with any other set of tubes, or with one another? Each of the two opinions implied in the question has had its advocates and defenders. But Du Hamel and Knight have shown that a branch will still continue to live though the tubes leading directly to it are cut in the trunk; from which it follows that the sap, though flowing the most copiously in the direct line of ascent, is at the same time also diffused in a transverse direction.

747. Causes of the sap's ascent. By what power is the sap propelled? Grew states two hypotheses: its volatile nature and magnetic tendency, aided by the agency of fermentation. Malpighi was of opinion that the sap ascends by means of the contraction and dilatation of the air contained in the air-vessels. M. De la Hire attempted to account for the phenomenon by combining together the theories of Grew and Malpighi; and Borelli, who endeavoured to render their theory more perfect, by bringing to its aid the influence of the condensation and rarification of the air and juices of the plant.

748. Agency of heat. Du Hamel directed his efforts to the solution of the difficulty, by endeavouring to account for the phenomenon from the agency of heat, and chiefly on the following grounds: because the sap begins to flow more copiously as the warmth of spring returns; because the sap is sometimes found to flow on the south side of a tree before it flows on the north side, that is, on the side exposed to the direct influence of heat; because the sap ascends the sun's heat sooner than on the side deprived of it; because plants may be made to vegetate even in the winter, by means of forcing them in a hot-house; and because plants raised in a hot-house produce their fruit earlier than such as vegetate in the open air. There can be no doubt of the great utility of heat in forwarding the progress of vegetation; but it will not therefore follow that the motion and ascent of the sap are to be attributed to its agency. On the contrary, it is very well known that if the temperature exceeds a certain degree, it becomes then prejudicial both to the ascent of the sap and also to the growth of the plant. Hales found that the sap flows less rapidly at mid-day than in the morning; and every body knows that vegetation is less luxuriant at midsummer than in the spring. So also, in the case of forcing, it happens but too often that the produce of the hot-house is totally destroyed by the unskilful application of heat; and if heat is actually the cause of the sap's ascent, how comes it that the degree necessary to prevent its ascension is so very variable? In the same respect it is surprising that there are so many plants, such as the arabis, laurustinus, and the mosses, that will continue not only to vegetate, but to produce their blossoms and mature their fruit, even in the midst of winter, when the temperature is at the lowest. And in the case of submarine plants the temperature can never be very high; so that although heat does no doubt facilitate the ascent of the sap by its tendency to make the vessels expand, yet it cannot be regarded as the efficient cause, since the sap is proved to be in motion even throughout the whole of the winter. Du Hamel endeavours, however, to strengthen the operation of heat by means of the influence of humidity, as being also powerful in promoting the ascent of the sap. The influence of the air and time of the day on the temperature of the atmosphere cannot be conceived to operate as a propelling cause, though it may easily be conceived to operate as affording a facility to the ascent of the sap in one way or other; which under certain circumstances it is extraneous, but powerful in that state of the atmosphere which forebodes or precedes a storm. In such a state a stalk of wheat was observed by Du Hamel to grow three inches in three days; a stalk of barley six inches, and a shoot of a vine almost two feet; but this is a state that occurs but seldom, and cannot be of much service in the general propulsion of the sap. On the other hand it appears to have been observed by Dumont that heat does not make an opinion very nearly allied to it; but does not seem to have strengthened it by any new accession of argument; so none of the hitherto alleged causes can be regarded as adequate to the production of the effect.

749. Irritability. Perhaps the only cause that has ever been suggested as appearing to be at all adequate to the production of the effect, is that alleged by Saussure. According to Saussure the cause of the sap's
grain, assisted perhaps by heat and humidity expanding or condensing the fluids. (Pd., Trans. 1801.) Keith considers this theory of Knight as beset with many difficulties, and the agency of the alleged cause as totally inadequate to the production of the effect to be accomplished.

751. Elaboration of the sap. The moisture of the soil is no sooner absorbed into the plant than it begins to undergo a change. This is proved by the experiment of making a bore or incision in the trunk of a tree during the season of bleeding; the sap that issues from the wound possesses properties very different from the mere moisture of the soil, as is indicated by means of chemical properties, and sometimes also by means of a peculiar taste or flavor, as in the case of the birch-tree. Hence the sap has already undergone a certain degree of elaboration; either in passing through the glands of the cellular tissue, which it reaches through the medium of a lateral communication, or in mingling with the juices contained in the cells, and thus carrying off a portion of them; in the same manner, we may suppose, that water by filtering through a mineral vein becomes impregnated with the mineral through which it passes. But this primary and incipient stage of the process of elaboration must always of necessity remain a mystery to the phytologist, as being wholly effected in the interior of the plant, and consequently beyond the reach of observation. All he can do, therefore, is to trace out its future progress, and to watch its succeeding changes, in which the rationale of the process of elaboration may be more evident.

752. The process of elaboration is chiefly operated in the leaf; for the sap no sooner reaches the leaf, than part of it is immediately carried off by means of perspiration, perceptible or imperceptible; effecting a change in the proportion of its component parts, and by consequence a change in its properties.

Hales reared a sun-flower in a pot of earth till it grew to the height of three feet and a half; he then covered the mouth of the pot with a plate of lead, which he cemented so as to prevent all evaporation from the earth contained in it. In this plate he fixed two tubes, the one nine inches in length and of but small diameter, communicating with the external air, and the other a tube of the same length and one in diameter, for the purpose of introducing a supply of water, but kept always shut except at the time of watering. The holes of the bottom of the pot were also shut, and the pot and plant weighed for the first time of July and again to the last day of October; the results of the transpiration of the leaves, from a comparison of the supply and waste; also the quantity of moisture transpired in a given time, by subtracting from the total waste the amount of evaporation from the pot. The final result proved that the absorbing power of the root is greater than the transpiring power of the leaves, the former being made in proportion to the number of cubes of calcareous earth whose mean transpiration was found to be 1 lb. 3 oz. per day; and on some species of evergreens, which were found, however, to transpire less than other plants. The same is the case also with succulent plants, which transpire but little in proportion to their mass, and which as they become more firm transpire less. It is known, however, that they absorb a great deal of moisture, though they give it out thus sparingly, which seems intended by nature for the purpose of resisting the great droughts to which they are generally exposed, inhabiting, as they do for the most part, the sandy desert or the sunny rock. Along with his other experiments Hales relates also some others that were made by Miller of Chelsea; the result of which was that, other circumstances being the same, transpiration is in proportion to the transpiring surface; and is affected by the temperature of the air, sunshine, or drought, promoting it, and cold and wet diminishing it. Even the greatest height of rock in the air is also greater near noon, and least during the night. But when transpiration becomes too abundant, owing to excess of heat or drought, the plant immediately suffers and begins to languish; and hence the leaves droop during the day, though they are again revived during the night. For the same or for a similar reason, transpiration has been found to be less in the last of summer advances; being more abundant in July than in June, and still more in August than in either of the preceding months, from which last period it begins again to decrease.

755. A fluid little different from common water is exhaled according to the experiments of Hales and Guettard; in some cases it had the odor of the plant; but Du Hamel found that it became sooner putrid than water. Such then are the facts that have been ascertained with regard to the imperceptible perspiration of plants, from which it unavoidably follows that the sap undergoes a very considerable modification in its passage through the leaf.

754. Perceptible perspiration, which is an exudation of sap too gross or too abundant to be dissipated immediately, and which hence accumulates on the surface of the leaf, is the cause of its further modification. It is very generally to be met with in the course of
the summer on the leaves of the maple, poplar, and lime-tree; but particularly on the surface exposed to the sun, which it sometimes wholly covers.

Its physical as well as chemical qualities are very different in various species of plants; so that it is not always merely an exudation of sap, but of sap in a high state of elaboration, or mingled with the peculiar juices or secretions of the plant. Sometimes it is a clear and watery fluid conglomering into large drops, such as are said to have been observed by Miller, exuding from the leaves of the muza arbor, or lime-tree; or, the liquid may be thick and cloudy, resembling cream, but leaving a stain on the poplar or willow, and trickling down in such abundance as to resemble a slight shower. This phenomenon was observed by Sir J. E. Smith, under a grove of willows in Italy, and is said to occur sometimes even in England. Sometimes it is glutinous, as on the leaf of the lime-tree; or, it is very decolorized, as in the orange-leaf; or; resinous, as on the leaves of the cistus croticus. The cause of this excess of perspiration has not yet been altogether satisfactorily ascertained; though it seems to be of an effort and instinct of nature to throw off all such redundant juices as may have been absorbed, secreted, or been formed for the purpose of the solitary water containing vegetable juices. But there are cases in which the exudation is to be regarded as an indication of disease, particularly in that of the exudation known by the name of honey-dew, a sweet and viscid substance covering the leaves like a varnish, and sometimes occasioning their decay. Such at least seems to be the case according to the account of Linnaus, the consequence of the attacks of the caterpillar of the ghost-moth injuring the root. And such seems also to be the fact with regard to the honey-dew of the bee-cherry, and perhaps also the honey-dew of the oak. The sap then in the progress of its ascent from the extremity of the root to the extremity of the leaf undergoes a considerable change, first in its mixing with the juices already contained in the plant, and then in its throwing off a portion at the leaf.

755. The sap is further affected by means of the gases entering into the root along with the moisture of the soil, but certainly, by means of the juices inhale into the leaf; the action and elaboration of which shall now be elucidated.

756. Elaboration of carboonic acid. The utility of carboonic acid gas as a vegetable food has been already shown; plants being found not only to absorb it by the root along with the moisture of the soil, but also by the leaves, as does the vegetating in the sun. The evaporating of this gas affected? Is it assimilated to the vegetable substance immediately apparently entering the plant, or is its assimilation effected by means of intermediate steps? The gas thus inhaled or absorbed is attacked by the plant and placed in the following ways: First, Priestley ascertained that plants vegetating in confined atmospheres evolve carboonic acid gas in the shade, or during the night, and that the vitiated state of their atmospheres after experiment is owing to that evolution; and Sauvage showed that the elaboration of carboonic acid gas is essential to vital phenomena. In sun; and, finally, it is shown that they form with the surrounding oxygen even in the dark. But the effect is operated chiefly by means of the leaves and other green parts of vegetables, that is, chiefly by the parenchyma; the wood, roots, petals, and leaves that have lost their green color not being found to exhale oxigenic acid. It may be observed, however, that the green color is not an absolutely essential character of the parts decomposing carboonic acid; because the leaves of a peculiar variety of the ariplex hortensis, in which all the green parts change to red, do still exhale oxigenic gas.

757. Elaboration of oxygen. It has been already shown that the leaves of plants absorb oxygen from confined atmospheres, at least when placed in the shade, though they do not inhale all the oxygen that disappears; and it has been further proved, from experiment, that the leaves of plants do also evolve a gas in the sun. From a great variety of experiments relative to the action and influence of oxygen on the plants, the following are the results. The green parts of plants, but especially the leaves, when exposed in atmospheric air to the successive influence of the light and shade, inhale and evolve alternately a portion of oxygen gas mixed with carboonic acid. But the oxygen is not assimilated to the vegetable substance; it is first converted into a gas different from oxygen by means of the acid by which the process is prevented by the application of lime or potash. The leaves of aquatics, succulent plants, and evergreens consume, in equal circumstances, less oxygen than the leaves of other plants. The roots, wood, and petals, and in short all parts not green, with the exception of some colored leaves, do not effect the successive influence of oxygen when they inhale it; and, though they do not again give it out, or assimilate it immediately, but convey it under the form of carboonic acid to the leaves, where it is decomposed. Oxygen is indeed assimilated to the plant, but not directly, and only by means of the decomposition of carboonic acid; when part of it, though in a very small proportion, is assimilated along with the carbon. Hence the most obvious influence of oxygen, as applied to the leaves, is that of forming carboonic acid gas, and thus preventing the plants elements which it may assimilate; and perhaps the carbon of the extractive juices absorbed even by the root, is not assimilated to the plant till it is converted by means of oxygen into carboonic acid gas. This process, which is promoted by the influence of nitrogen and carboonic acid gas only is not favorable to vegetation, it is probable that oxygen performs also some other function beyond that of merely presenting to the plant, under the modification of carboonic acid, elements which it may assimilate. It may effect also the disengagement of the carbon of the carboonic acid, which the plants need. But oxygen is also beneficial to the plant from its action on the soil; for when the extra juices contained in the soil have been exhausted, the oxygen of the atmosphere, by penetrating into the earth and abstracting from it a portion of its carbon, forms a new extract to supply the deficiency. But the root of this supply, observed by a number of facts observed by the experimenters, but not well explained. Du Hamel remarked that the lateral roots of plants are always the more vigorous the nearer they are to the surface; but it now appears that they are the most vigorous at the surface because they have there the easiest access to the oxygen of the air, or to the exhalation of the earth, or to the direct influence of the sun. However, that perpendicular roots do not thrive so well, other circumstances being the same, in a stiff and wet soil as in a friable and dry soil; while plants with slender and divided roots thrive equally well in both: but this is no doubt owing to the obstacles that present themselves to the greater depth of the root, to the water remaining after a storm, for what is called the fox-tail root; but it is because they cannot continue to vegetate, except by increasing their points of contact, with the small quantity of oxygen found in such medium. Lastly, it was observed that plants, whose roots are suddenly overflowed with water remaining afterwards stagnant, suffer sooner than if the accident had happened by means of a continued current. It is because in the former case the oxygen contained in the water is soon exhausted, while in the latter it is
not exhausted at all. And hence also we may account for the phenomenon exhibited by plants vegetating in distilled water under a receiver filled with atmospheric air, which having no proper soil to supply the root with nourishment, effect the development of their parts only at the expense of their own proper substance; the interior of the stem, or the action of the root, or the lower leaves decaying and giving up their extractive juices to the other parts. — Thus it appears that oxygen gas, or that constituent part of the atmospheric air which has been found to be indispensable to the life of animals is also indispensable to the life of vegetables. But although the presence and action of oxygen is absolutely necessary to the process of vegetation, plants do not thrive so well in an atmosphere of pure oxygen, as in an atmosphere of pure or common air. This was proved by an experiment of Saussure's, who having introduced some plants of pisum sativum, that were but just issuing from the seed, into a receiver containing pure oxygen gas, found that of ten days' duration only half the weight of such as were introduced at the same time into a receiver containing common air. From whence it follows that oxygen, though the principal agent in the process of vegetation is not yet the only agent necessary to the health and growth of the plant, and that the proportion of the constituent parts of the atmospheric air is well adapted for the process of both vegetable and animal life.

758. Decomposition of water. Although the opinion was proved to be groundless, by which water had been supposed to be convertible into all the different ingredients entering into the composition of the vegetable substance by means of the action of the vital energy of the plant; yet when water was ultimately proved to be a chemical compound, it was by no means absurd to suppose that plants may possess the power of decomposing part, at least, of what they absorb by the root, and thus acquire the hydrogen as well as a portion of the oxygen which, by analysis, they are found to contain. This opinion was accordingly pretty generally adopted, but was not yet proved by any direct experiment. Senebiier pointed out several phenomena from which he thought it was to be inferred, but particularly that of the germination of some seeds moistened merely with water, and so situated as to have no apparent contact with oxygen. The decomposition of water was inferred also by Ingenhouz, from the amelioration of an atmosphere of common air into which he had introduced some succulent plants vegetating in pure water. Saussure having gathered a number of plants of the same species, as nearly alike as possible in all circumstances likely to be affected by the experiment, dried part of them to the temperature of the atmosphere, and ascertained their weight; the rest he made to vegetate in pure water, and in an atmosphere of pure oxygen for a given period of time, at the end of which he dried them as before, and ascertained their weight also, which it was thus only necessary to compare with the weight of the former, in order to know whether the plants had increased in solid vegetable substance or not. But after many experiments on a variety of plants, the result always was, that plants when made to vegetate in pure water only, and in an atmosphere of pure oxygen, or of common air deprived of its carbonic acid, scarcely added any thing at all to their weight in a dried state; or if they did, the quantity was too small to be appreciated. But from a subsequent experiment, in which carbonic acid gas was mixed with common air by the same experiment, the decomposition and fixation of water by the vegetating plant is legitimately inferred. It does not appear, however, that plants do in any case decompose water directly; that is, by appropriating its hydrogen and at the same time disengaging its oxygen in the form of gas, which is extricated only by the decomposition of carbonic acid.

759. Descent of the proper juice. When the sap has been duly elaborated in the leaf by means of the several processes that have just been described, it assumes the appellation of the cambium, or proper juice of the plant. In this ultimate state of elaboration it is found chiefly in the bark, or rather between the bark and wood, and may very often be distinguished by a peculiar color, being sometimes white, as in the several species of spurge, and sometimes yellow, as in celandine. It is said to be the principal seat of the medical virtues of plants; and was regarded by Malphigii as being to the plant what the blood is to the animal — the immediate principle of nourishment, and grand support of life; which opinions he endeavours to establish by the following analogies: if the blood escapes from the vessels of the animal body, it forms neither flesh nor bone, but tumors; if the proper juices of the plant are extravasated, they form neither bark nor wood, but a lump of gum, resin, or inspissated juice. The disruption of the blood-vessels and consequent loss of blood, injures and often proves fatal to the animal. The extravasation of the proper juice injures and often proves fatal to vegetables, unless the evil is prevented by the skill and management of the gardener. Whatever may be the value of these remarks as tending to establish the analogy in question, it cannot be doubted that the cambium or proper juice constitutes at least the grand principle of vegetable organisation; generating and developing in succession the several organs of the plant, or furnishing the vital principle with the immediate materials of assimilation.

760. The proper juice is conveyed to the several parts of the plant by an appropriate set of vessels. One of the earliest and most satisfactory experiments on this subject, at least as far as regards the return of the proper juice through the leaf and leaf-stalk, is that of Dr. Darwin, which was conducted as follows: a stalk of the euphorbia helioscopia, furnished with its leaves and seed-vessels, was placed in a decotion of madder-root, so as that the lower portion of the stem and two of the inferior leaves were immersed in it. After remaining so for several days the color of the decotion was distinctly discerned passing along the midrib of each leaf. On the upper side of the leaf many of the ramifications, going from the midrib towards the circumference, were observed to be tinged with red; but on the under side there was observed a system of branching vessels, originated in the extremities of the leaf and carrying not a red but a pale milky fluid, which, after uniting in two sets, one on each side the midrib, descended along with it.
into the leaf-stalk. These were the vessels returning the elaborated sap. The vessels observable on the upper surface Darwin calls arteries, and those on the under surface he calls veins. To this may be added the more recent discoveries of Knight and of his coadjutors, with a view to ascertain the course of the sap, detected in the leaf-stalk, not only the vessels which he calls central tubes, through which the colored infusion ascended, together with their appendages, the spiral tubes; but also another set of vessels surrounding the central tubes, which he distinguishes by the appellation of external tubes, and which, in his opinion, are the intermedia, in the direction of the outer border of the leaf; and which he has, upon further investigation, determined to be the descending proper juice. In tracing them upwards they were found to extend to the summit of the leaf, and in tracing them downwards they were found to penetrate into the foot-stalk and the central tubes, and the portion of the plant to which the leaf is attached. But what by means is the proper juice conducted from the base of the leaf-stalk to the extremity of the root? This was the chief object of the enquiry of the earlier physiologists who had not yet descanted into peculiarities in this respect; but what Knight was to discover in the ascension to at least the descent of a fluid in the trunk. Du Hamel stated sixty trees of their bark in the course of the spring, laying them bare from the upper extremity of the sap and branches to the root; the experiment proved indeed fatal to them, as they all died in the course of three or four years. But many of them had been stripped without from the buds or twigs upwards, excepting the length of a foot; though very few of them had made any new productions from the root upwards. Hence it is that the proper juice not only descends from the extremity of the leaf to the extremity of the root, but generates also in its descent new and additional parts. The experiments of Knight on this subject are, if possible, more convincing than even those of Du Hamel. From the trunks of a number of young crab-trees he detached a ring of bark of half an inch in breadth. The sap rose in them, and the portion of the trunk above the ring augmented as in other subjects that were not so treated, while the portion below the ring scarcely augmented at all. The upper lips of the wounds made considerable advances downwards, while the lower lips made scarcely any advances upwards; but if a bud was protruded under the ring, and the shoot arising from it allowed to remain, then the portion of the trunk below that bud began immediately to augment in the same manner as the portion above while the bud and incision remained untouched. When two circular incisions were made in the trunk so as to leave the twem them with a leaf growing from it, the portion above the leaf died, while the portion below the leaf lived; and when the upper part of a branch was stripped of its leaves the bark withered as far as it was stripped. Whence it is that Knight has been enabled to assert that the leaf is the head of the shoot and converted into proper juice, descends through the channel of the bark, or rather between the bark and alburnum to the extremity of the root, effecting the development of new and additional parts. But not only is the bark thus ascertained to be the channel of the descent of the proper juice, after entering the trunk; the vessels which accompany the trunks have been found by the mode of analysis of Knight they are merely a continuation of the external tubes already noticed, which after quitting the base of the foot-stalk he describes as not only penetrating the inner bark, but descending along with it and conducting the proper juice to the very extremity of the root. From the large vessels of Mirbel and external tubes of Knight, they are the larger or rather simple tubes so abundant in the bark of woody plants, though not altogether confined to it; and so well adapted by the width of their diameter to afford a passage to the proper juice.

761. Causes of descent. The proper juice then, or sap elaborated in the leaf, descends by the returning vessels of the leaf-stalk, and by the longitudinal vessels of the inner bark, the large tubes of Mirbel and external tubes of Knight, down to the extremity of the root. The descent of the proper juice was regarded by the earlier physiologists as resulting from the agency of gravitation, owing perhaps more to the readiness with which the conjecture suggests itself to than to the satisfaction which it gives. But the insufficiency of this cause was clearly pointed out by Du Hamel, who observed in his experiments with ligatures that the tumor was always formed on the side next to the leaves, even when the branch was bent down whether by nature or art, so as to point to the earth, in which case the power propelling the proper juice is acting not only in opposition to that of gravitation, but with such force as to overcome it. This is an unanswerable argument; and yet it seems to have been altogether overlooked, or at least undervalued in its importance. The chief end of the experiment is in describing the causes of gravitation, capillary attraction, the waving motion of the tree, and the structure of the conducting vessels; but the greatest of these causes is gravitation. Certain it is that gravitation has considerable influence in the descent of the proper juice which hastens to the roots in young trees when bent down after being fully grown, form larger buds, and often blossom instead of leaf buds. This practice, with a view to the production of blossom-buds is frequently adopted by gardeners (Hort. Trans. i. 257.) in training fruit-trees. These causes are each perhaps of some efficacy; and yet even when taken together they do not seem sufficient to propel the proper juice into the roots. The action of the silver grain will scarcely be sufficient to propel it; and if it should be said that the sap ascends through the tubes of the alburnum by means of the agency of the vital principle, why may not the same vital principle conduct also the proper juice through the returning vessels of the bark. In short if, with Saussure, we admit the existence of a contracting power in the former case sufficient to propel the sap from root to spring, it will be absolutely necessary to admit it also in the latter. Thus we assign a cause adequate to the production of the effect, and avoid at the same time the transgression of that most fundamental principle of all sound philosophy which forbids us to multiply causes without necessity.

Sect. IV. Process of Vegetable Development.

62. The production of the different parts and organs of plants is effected by the assimilation of the proper juice. The next object of our enquiry, therefore, will be that of tracing out the order of the development of the several parts, together with the peculiar mode of operation adopted by the vital principle. But this mode of operation is not exactly the same in herbaceous and annual plants, as in woody and perennial plants. In the former, the process of development comprises as it were but one act of the vital principle, the parts being all unfolded in immediate succession and without any perceptible interruption till the plant is complete. In the latter, the process is carried on by gradual and definite stages easily cognizable to the senses, commencing with the approach of spring, and terminating with the approach of winter; during which, the functions of the vital principle seem to be altogether suspended, till it is aroused again into action by the warmth of the succeeding spring. The illustration of the latter, however, involves also that of the former; because the growth of the first year exemplifies at the same time the
Chapter I.

PROCESS OF VEGETABLE DEVELOPMENT.

173

growth of annuals, while the growth of succeeding years exemplifies whatever is peculiar to perennials.

763. Elementary organs. If the Embryo, on its escape from the seed and conversion into a plant, is taken and minutely inspected, it will be found to consist of a root, plumule, and incipient stem, which have been developed in consecutive order; and if the plant is taken and dissected at this period of its growth it will be found to be composed merely of an epidermis enveloping a soft and pulpy substance, that forms the mass of the individual; or it may be furnished also with a central and longitudinal fibre; or with bundles of longitudinal fibres giving tenacity to the whole. These parts have been developed without doubt by means of the agency of the vital principle operating on the proper juice; but what have been the several steps of operation?

764. Composite organs. The elucidation of the development of the composite organs involves the discussion of the two following topics: — the formation of the annual plant, and of the original shoot of the perennial; and the formation of the subsequent layers that are annually added to the perennial.

765. Annuals and annual shoots. If a perennial of a year’s growth is taken up in the beginning of winter when the leaves, which are only temporary organs, have fallen, it will be found to consist of a root and trunk, surmounted by one or more buds. The root is the radicle expanded into the form peculiar to the species, but the trunk and buds have been generated in the process of vegetation.

766. The pith seems only a modification of the original pulp, and the same hypothesis that accounts for the formation of one will account also for the formation of the other; but the pith and pulp, or parenchyma, are ultimately converted into organs essentially distinct from one another; though physiological opinions have been much puzzled to assign to each its respective functions. In the ages in which physiological opinions were formed without enquiry, one of the vulgar opinions of the time seems to have been that the pith was supposed to be that of generating the stone of fruit, and by which it was thought that a tree deprived of its pith would produce fruit without a stone. Phys. des Arb. liv. i. chap. 3.) But this opinion is by much too absurd to merit a secondary refutation. Another equally false is that by which the pith is regarded as being analogous to the heart and brain of animals, as related by Malpighi; who did not himself adopt it, but believed the pith to be like the cellular tissue, the vasa in which the sap is elaborated for the nourishment of the plant, and for the promotion of future buds. Magend thought that it produced the same effect, and De Hamel regarded it as being merely an extension of the pulp or cellular tissue, without being destined to perform any important function in the process of vegetable. But Linnaeus was of opinion that it produces even the wood; regarding it not only as the source of vegetable nourishment, but also as the vegetable part of the brain and animal marrow are of the animals, the source and seat of life. In these opinions there may be something of truth, but they have all the common fault of ascribing to the pith either too little or too much. M. Lindsay of Jamaica suggested a new opinion on the subject, regarding it as being the seat of the irritability of the leaves of the pine, and Sir J. F. Smith says he can nothing to invalidate the arguments on which this opinion is founded. Flenk and Knight regard it as destined by nature to be a reservoir of moisture to supply the leaves when exhausted by excess of perspiration. Hence it appears that the peculiar function of the pith may not be altogether satisfactorily ascertained; and the difficulty of ascertaining it has been thought to be increased from the circumstance of its seeming to be only of a temporary use in the process of vegetation, by its disappearing altogether in the aged trunk. But although it is thus only temporary as relative to the body of the trunk, yet it is by no means temporary as relative to the process of its development. In other parts being now in a vegetative state, the pith is being always present in one shape or other in the annual plant, or in the new additions that are annually made to perennials. The pith then is essential to vegetation in all its stages; and from the analogy of its structure to that of the cellular tissue, it is known to have been in operation in the leaf, the function of the pith is most probably that of giving some peculiar elaboration to the sap.

767. The generation of the layer of wood in woody plants, or of the parts analogous to wood in the case of herbaceous plants, has been hitherto supposed to be the result of the development of different parts to exist already in the embryo, then we have only to account for their development by means of the intro-suggestion and assimilation of sap and proper juice; but if we suppose them to be generated in the course of vegetation, then the difficulty of distinguishing the one and the other has been so long continued as to present an effect cognizable to the sense of sight, though the detail of the process is often so very minute as to escape even the nicest observation. All, then, that can be said on the subject, is merely that the tubes, however formed, do, by virtue of the agency of the vital principle operating on the proper juice, always make their appearance last in a uniform and determinate manner, according to the tribe or species to which the plant belongs, uniting and coalescing so as to form either a circular layer investing the pith, as in woody plants; or a number of divergent layers intersecting the pith, as in some herbaceous plants; or bundles of longitudinal
and woody fibre interspersed throughout the pith, as in others. In the same manner we may account for the formation of the layer of bark.

768. Perennials and their annual layers. If a perennial is taken at the end of the second year and dissected as in the example of the first year, it will be found to have increased in height by the addition of a perpendicular shoot consisting of bark, wood, and pith, as in the shoot of the former year; and in diameter by the addition of a new layer of wood and of bark, generated between the wood and bark of the former year, and covering the original core of wood, like the paper that covers a sugar-loaf: this is the fact of the mode of augmentation about which physiologists have not differed, though they have differed widely with regard to the origin of the additional layer by which the trunk is increased in diameter. Malpighi was of opinion that the new layer of wood is formed from the inner of the former year.

769. The new layer of wood. Linnæus considered as formed from the pith, which is absurd, because the opinion goes to the inversion of the very order in which the layer is formed, the new layer being always exterior to the old one. But according to the most general opinion, the layer was thought to be formed from a substance cooing out of the wood or bark—first, a limpid fluid, then a viscid pulp, and then a thin layer attaching itself to the former; the substance exuding from the wood or bark was generally regarded as being merely an extraneous cambium, which was supposed to be otherwise converted into new layer of bark: but Du Hamel regarded it as being already an organised substance, consisting of both cellular and tubular tissues, which he designated by the application of the cambium, or proper juice.

770. Knight has thrown the highest degree of elucidation on this, one of the most obscure and intricate processes of the vegetable economy, in a having shown that the sap is elaborated, so to render it fit for the formation of new parts in the leaf only. If a leaf or branch of the vine is grafted even on the fruit-stalk or tendril, the graft will still succeed; but if the upper part of a branch is stripped of its leaves the bark will wither as far as it is stripped; and if a portion of bark furnished with a leaf is insulated by means of detached branches above and below, the part of the wood in the insulated portion of the shoot is not augmented: this shows evidently that the leaf gives the elaboration necessary to the formation of new parts, and that without the agency of the leaf no new part is generated:—Such then is the mode of the formation of the leaf of its growth, and extension year by year, firstly of wood and of bark insinuated between the wood and bark of the former year; and in height by the addition of a perpendicular shoot, or of branches, generated as in the shoot of the first year. But if the plant is taken and dissected at the end of the third year, it will be found to have augmented its length; and at the end of the fourth year, it will have become fit to live; so that the outermost layer of bark, and innermost layer of wood, must have been originally tangential in the first year of the plant’s growth; the second layer of bark, and second layer of wood, in the second year; and so on in the order of succession till you come to the layer of the present year, which will in like manner divide into two portions, the outer forming one or more layers of bark, and the inner forming one or more layers of wood. And hence the origin of the concentric layers of wood and of bark of the trunk. But how are we to account for the formation of the divergent layers, which Du Hamel contended to be formed from the true solution of the sap? The difficulty was overcome by Knight, who, in tracing the result of the operation of budding, observed that the wood formed under the bark of the inserted bud unites indeed confusedly with the stock, though still possessing the character and properties of the wood from which it was taken, and exhibiting divergent layers of new formation which commence within the line of union, and extend to the bark, and outermost layer of wood, at the time of the formation of the shoot.

771. But how is the formation of the wood that now occupies the place of the pith to be accounted for? It appears that the tubes of which the medullary is composed do, in the process of vegetation, deposit a cambium, which forms an interior layer that is afterwards converted into wood for the purpose of filling up the medullary canal.

772. Conversion of the alburnum into perfect wood. In consequence of the increase of the trunk by means of the regular and gradual addition of an annual layer, the layers whether of wood or of bark are necessarily of some portion in proportion to their age; the inner layer of bark, and the outer layer of wood, being the softest; and the other layers increasing in their degree of solidity till you reach the centre on the one hand, and the circumference on the other, where they are respectively the hardest, forming perfect wood or highly indurated bark, which sloughs or splits into chinks, and falls off in thick crescentic plates, flar, and in the angle requisite to that layer that is deposited into perfect wood, or the liber into indurated bark; and by what means are they so converted? There is no fixed and definite period of time that can be positively assigned as necessary to the complete induration of the wood or bark, though it seems to require a period of a good many years before any particular layer is converted from the state of alburnum to that of perfect wood; and perhaps no layer has received its final degree of induration till such time as the tree has arrived at its full growth. The induration of the alburnum, and its consequent durability, are attributed by many to the loss of sap which the layer sustains after the completion of its development; when the supply from the root diminishes, and the waste by evaporation or otherwise is still kept up, inducing a contraction or condensation of its elementary principles that augments the solidity of the layer, in the first degree, and begins the process that future years finish. But Knight believes the induration of the alburnum as distinguishable in the different layers of a tree, rather to be deposited in little detached crescents of tissue deposited in little detached crescents of tissue, some of which he regards as being the proper juice in a concrete or inspissated state, but which is carried off again by the sap as it ascends in the spring.

773. Circulation of vegetable juices. After the discovery of the circulation of the blood of animals, phytologists, who were fond of tracing analogies between the animal and vegetable kingdoms, began to think that there perhaps existed in plants also a circulation of fluids. The sap was supposed to be elaborated in the root. The vessels in which it was propelled to the summit of the plant were denominated arteries; and the vessels in which it is again returned to the root were denominated veins. Du Hamel, while he admits the ascent of the sap, and descent of the proper juice, each in peculiar and appropriate vessels, does not however admit the doctrine of a circulation; which seems, about the middle of the last century, to have fallen into disrepute. For Hales, who contended for an alternate ascent and descent of fluids in the day and night, and in the same vessels, or for a sort of vibratory motion as he also describes it, gave no countenance whatever to the doctrine of a circulation of juices. But the doctrine, as it appears, has been again revived, and has met with the support of some of the most distinguished of
modern phytologists. Hedwig is said to have declared himself to be of opinion, that plants have a circulation of fluids similar to that of animals. Corti is said to have discovered a species of circulation in the stem of the charm, but confined, it is believed, within the limits of the internodia. Willdenow has also introduced the subject, and defended the doctrine (Principles of Botany, p. 85.); but only by saying he believes a circulation to exist, and that it is impossible for the leafless tree to resist the cold if there be not a circulation of fluids. Knight has given his reasons somewhat in detail; and though his doctrine of a circulation should be false, yet the account which he gives of the progress and agency of the sap and proper juice, short of circulation, may be true. The sum of the account is as follows: When the seed is deposited in the ground under proper conditions, moisture is absorbed and modified by the cotyledons, and conducted directly to the radicle, which is by consequence first developed. But the fluid which has been thus conducted to the radicle, mingling no doubt with the fluid which is now also absorbed from the soil, ascends afterwards to the plumule through the medium of the tubes of the alburnum. The plumule now expands and gives the due preparation to the ascending sap, returning it also in its elaborated state to the tubes of the bark, through which it again descends to the extremity of the root, forming in its progress new bark and new alburnum; but mixing also, as he thinks, with the alburnum of the former year, where such alburnum exists, and so completing the circulation.

774. Decomposite organs. To the above brief sketch of the agency of the central principle in the generation or growth of the elementary and composite organs, there now remains to be added that of the progress and mode of the growth of the decomposite organs, or organs immediately constituting the plant, as finishing the process of the vegetable development. This will include the phenomena of the ultimate development of the root, stem, branch, bud, leaf, flower, and fruit.

775. The root. From the foregoing observations and experiments, it appears that the roots of plants, or at least of woody plants, are augmented in their width by the addition of an annual layer, and in their length by an additional length of the existing root, bursting from the terminating fibre. But how is the development of the shoot effected? Is it by the same or a similar process as that which goes on throughout the whole plant, or by effects external to it? In order to ascertain the fact, with regard to the elongation of the root, Du Hamel instituted the following experiment:—Having passed several threads through the stem of a plant, and by the distends of a pestle, conveyed them to the root in water. The upper threads retained always their relative and original situation, and the lowest thread which was placed within a few lines of the end was the only one that was carried down. Hence he concluded that the root is elongated merely by the extremity. Knight, who from a similar experiment obtained the same conclusion, did not agree in that conclusion. We may, however, ask if Du Hamel's results sufficiently allow us to believe that the mode of the elongation of the root is such as is here represented, though in the progress of its development, it may affect a variety of directions. The original direction of the root is generally perpendicular, as to its growth, but not so with the accessory, or branch, root which is inserted from the base of the same, the root being broader at its commencement, or where it begins to divide into branches, being broader than at the extremity. In taking up some young oak-trees that had been planted in a poor soil, Du Hamel found that the root had descended almost four feet, while the height of the trunk was not more than six inches. If the root meets with an obstacle it then takes a horizontal direction, not by the bending of the original shoot, but by the sending out of branches. If the root it will not meet with difficulty, it is perpendicular; but it is otherwise directed, so, for it is a common thing in nursery-gardens, to cut off the tap-roots of drills of seedling oaks without removing them, by a sharp spade, and these generally push out new tap-roots, though not so strong as the former ones, so that a root of its length is necessary to elongate, it sends out also lateral fibres which become branches, and are always the more vigorous the nearer they are to the trunk, but the horizontal fibres or branches are the less vigorous the nearer they are to the end next the trunk. In the former case, the increased luxuriance is perhaps owing to the easy access of oxygen in the upper divisions; but in the latter case, its increased luxuriance is owing to the greater distants of its insertion, and having the easier distants of its insertion, not so easily accounted for, if it is not to be attributed to the same ample supply of nutriment which the fibres meet with as they recede from the trunk, particularly if you suppose a number of them lying horizontally and diverging like the radii of a circle. But the direction of the roots is so liable to be affected by accidental causes, that there is often but little uniformity even in roots of the same species. If plants were to be sown in a soil of the same density throughout, perhaps there might be at least as much uniformity in the figure and direction of their roots, as of their branches; but this will seldom happen. For if the root is injured by the attacks of insects, or interrupted by stones, or earth of too dense a quality, it then sends out lateral branches, as in the above cases; sometimes extending also in length by following the direction of the obstacle, and sometimes ceasing to elongate, and forming a knot at the extremity. But where the soil has been loosened by digging or otherwise, the root generally extends itself to an unusual length, and where it is both loosened and enriched with organic substances, it is also thicker and broader. This is the case of roots which grow in a pot, near a river, or especially in water. Where roots have some considerable obstacle to overcome they will often acquire a strength proportioned to the difficulty; sometimes they will penetrate through the hard fleshy parts of a fruit, sometimes they will penetrate through the crevices even of walls and rocks which they will burst or overturn. This of course requires much time, and does much injury to the plant. Roots consequently thrive best in a soil that is neither too loose nor too dense; but as the nourishment which the root absorbs is chiefly taken up by the extremity, so the soil is often more exhausted at some distance from the trunk than immediately around it. The latter part of the trunk the nourishment absorbed by the smaller fibres, which ascending by the tubes of the alburnum, is thus conveyed to the leaves, the digestive organs of plants. Du Hamel thinks that the roots of plants are furnished with a number of vessels, or channels through which they are conveyed, which is thought by several, though the existence of such germs is not proved; and affirms that the extremities of the fibres of the root die annually like the leaves of the trunk and branches, and are again annually renewed; which last peculiar circumstance Willdenow affirms also to be the fact, but without adding any evidence by which it appears to be satisfactorily substantiated. On the contrary, Knight, who has also made some observations on this subject, says, it does not appear that the terminating fibres of the roots of woody plants die annually, though those of bulbous roots are found to do so. But the fibres of creeping plants, as the common crowfoot and strawberry, certainly die annually, as does that of the vine.
The stem. The stem, like the root, or at least the stem of woody plants, is also augmented in width by the addition of an annular layer, and in length by the addition of an annual shoot bursting from the terminable bud. Is the development of the shoot issuing in the first instance, like the root, to a secondary stem, or is it developed as an addition to the shoot issuing in the first instance, like the root, to a secondary stem issuing in the second instance, or is it developed as an addition to the shoot issuing in the second instance, like the root, to a secondary stem issuing in the third instance, and so on ad infinitum? The development of the shoot from the stem is not affected in the same manner as that of the root—by additions to the extremity only, but by the intra-suggestion of additional particles throughout its entire length. The stem, at its own extremity, acquires a portion of the shoot as the shoot acquires solidity, and ceasing entirely when the wood is perfectly formed; though often continuing after it has ceased at the base. The extension of the shoot is inversely as its induration, rapid while it remains herbaceous, but slow in proportion as it is converted into wood. Hence to preserve the shoot, because they propagate by its elongation, is not so much a question of its induration; and hence the small cone of wood which is formed during the first year of the plant's growth increases more and more after the approach of winter, neither in height nor thickness. Such is the mode of the gradual increase of the stem in length and width, to which constant exception in the growth of the trunk of palms. Their internal structure has been already taken notice of as presenting no concentric or divergent layers, and no medullary canal, but merely an assemblage of large and woody fibres, interspersed without order in a pulp or parenchyma, softer at the centre and gradually becoming harder as the bark is approached. When the bark has increased in thickness, it produces a circle of cells, which may constitutes a circular row of leaves, or of fronds, which crowns the radicle, and is succeeded in the following year by a similar row issuing from the centre or bosom of the former leaves, which ultimately die down to form the bud, which in the beginning of spring is vested for four or five years successive for or during as yet any appearance of a stem, the remains being of the leaves or fronds forming by their union merely a sort of knob or bulk. At last, however, they constitute by their union an incipient stem, as thick the first year as it is ever after; which in the following year is augmented in height as before, and so on in succession as long as the plant lives, the leaves always issuing from the summit and crowning the stem, which is a regular column, but decaying at the end of the year, and leaving circular marks at the points of insertion, which furrow the surface of the plant, and indicate the years of its growth.

The branches, in their mode of growth and development, exhibit nearly the same appearance as the trunk issuing in a bud, and issuing from a bud in a shoot, but they form a cone that consists of pitch, wood, and bark; or rather they form a double cone. For the insertion of the branch into the trunk resembles also a cone whose base is at the circumference, and whose apex is at the centre, at least if it is formed by the primary shoot at the end of the plant of the year; though, perhaps, the centre in proportion to the lateness of its formation, and number of intervening layers. Branches in their development assume almost all varieties of position from the reflected to the horizontal and upright; but the lower branches of trees are said to be generally parallel to the surface of the soil on which they grow, every branch as it were a shoot of a hill—owing, as it has been thought, to the economical distribution of a greater number of buds on the side that forms the obtuse angle with the soil, in consequence of its being exposed to the action of a greater mass of air.

The leaves of the tree in the spring is so conspicuous on the trees of this country as to be obvious to the most careless observer, is by no means common to all plants, nor to plants of all climates; shrubs in general, and annuals, universally, are destitute of buds as well as all plants whatever growing within the tropics, the leaf being in them immediately protruded from the bark. It is only in the woody plants of cold climates, therefore, that we are to look for buds; and in them no new part is added proper to the leaf or flower, without the intervention of a bud. For when the young shoot is produced, it is at the same time furnished with new buds, which are again extended into new shoots in the following spring; and thus the bud is to be regarded as forming, not only the cradle but also the winter quarters of the plant. In this respect it is very well adapted for serving the purpose of the bud in the exterior, or on the surface of the young shoot or branch, and but rarely on the stem, except in the collar where it produces suckers. It is also generated for the most part in the axil of the leaves, as may be seen by inspecting the annual shoot of almost any tree at random, though not universally so; for to this rule there exists a curious and singular exception in the bud of the plataneus, which is generated in the very centre of the base of the foot-stalk, and is not discoverable till after the fall of the leaf. But how are the buds formed which are thus developed? Malpighi thought they were formed from the pith or cellular tissue, which the latter regarded as viscera destined for the elaboration of the sap and preparation of future buds. Du Hamel thinks the exterior scales of the bud originate in the interior part of the bark, and Knight relates an experiment from which he thinks it follows that the buds are formed from the cambium only by proper junctures of the members of the cambium at the point of juncture with the bud. The effect perhaps of their peculiar structure of being formed of parallel tubes which extend throughout their whole length, without those transverse and branching fibres that constitute what are called the nerves of the leaves of woody plants.

The flower and fruit. When the flower bursts from the expanding bud, and even long before that period, it is already complete in all its parts, as may be seen by the dissection of the bud in the winter, they are complete in all their parts. Hence it is obvious that the leaf, like the young shoot, effects its final development by means of the intra-suggestion of new particles throughout the whole of its dimensions: and yet this law of development is not common to leaves whatever, for the leaves of the cryptozoids plants extend outwards at the point of juncture with the bud. The effect perhaps of their peculiar structure of being formed of parallel tubes which extend throughout their whole length, without those transverse and branching fibres that constitute what are called the nerves of the leaves of woody plants.

When the flower bursts from the expanding bud, and even long before that period, it is already complete in all its parts, as may be seen by the dissection of the bud in the winter. Linnaeus represents the pistil as originating in the pith, the stamens in the wood, and the corolla and calyx in the medullary tissue, and outer bark respectively; but this account of their origin, though extremely plausible at first sight, will not bear the test of minute dissection, being contradicted by the anatomist, being contradicted by themselves; particularly in the case of compound flowers. Knight in investigating the organisation of the apple and pear, endeavoured to ascertain the origin of the several parts by tracing the organs of the fruit-stalk to their termination. In the fruit-stalk he thought he could discover the pith, the central tubes, spiral tubes, and tubes of the bark, together with their epidermis: and in tracing them to their termination, he thought the pith seemed to end in the pistils; the central vessels in the stamens, after dividing, to the core and appearing again in the eye of the fruit; and the bark and epidermis in the external skins. Hence he inferred that the flower is a product of the entire pith and cortex of the stem.

A question of some considerable importance has arisen out of this subject: does the flower or fruit elaborate sap for its own development, or is it supplied with nourishment from the leaf? By placing small branches over the bud, and watching the processes of its development, it was found that the central vessels were colored by the decocation. By means of a similar experiment on the same subjects after the fruit was formed, the coloring matter was traced through the mass of the fruit to the base of the stamens. And hence it appears that the flower and fruit do possess the power of elaborating sap. Johnson goes even further, and states that the pith and cortex are derived from the former by a process of elongation, the branches from the albumen, by means of the minging of the proper juice, which the albumen may be supposed to contain with the sap in its ascent.
Sect. V. Anomalies of Vegetable Development.

781. A deviation from the general laws of development is occasioned by the intervention of some accidental cause; or of some cause operating permanently in certain subjects. Hence the anomaly may regard the development either of an individual or a species, and may occur either in the root, stem, branch, leaf, bud, flower, or fruit, according to the circumstances in which it is placed; or it may affect the habit, duration, or physical virtues of the plant.

782. The root. According to the general laws of vegetable development, plants of the same species are furnished with the same species of root—not producing at one time a woody or fibrous root, and at another time a bulbous root. And yet it is found that there are cases in which changes of this kind do occur. If part of the root of a tree planted by a pond or river, protrudes beyond the bank so as to be partially immersed, it divides at the extremity into innumerable ramifications, or sends out innumerable fibres from the surface, which become again subdivided into fibres still more minute, and give to the whole an appearance something resembling that of the tail of a fox; which has accordingly been denominated by Du Hamel the fox-tail-root. (fig. 57.)

783. The root of the Phlomis pratensis, when growing in a moist soil, which is not uniformly fibrous, but when growing in a dry soil, where it is also often to be found, it is furnished with a bulbous root. The same is the case with the alopecurus geniculatus; which, when growing in its native marshes protrudes a fibrous root, though, when growing in a very dry situation, as on the top of a dry wall, it is found to be furnished with an ovate and juicy bulb.

784. The roots of Utricularia minor, which consist of a number of slender and hair-like filaments, exhibit the singular anomaly of being furnished with a multitude of small and membranous bladders, each containing a transparent and watery fluid, and a small bubble of air, by means of which the plant is kept floating in the water.

785. The descending root, an anomaly which attends some perennialS, is at first spindle-shaped and perpendicular, sending out some lateral fibres; but dying at the lower extremity in the course of the succeeding winter, and protruding the remaining portion of new fibres, and even from the lower portion of the stem, in the course of the following spring, which by descending into the soil, draw down the plant with them, so that part of what was formerly stem is now converted into root. This process is repeated every year, and by consequence a portion of the stem is made to descend every year into the earth. The anomaly may be exemplified in the roots of valeriana dioica, tanacetum vulgare, and oxalis acetosella; and will also account for the bitten and truncated appearance of scabiosa succincta, or devil's-bit.

786. The boot-root, if dissected when about a year old, presents the singular anomaly of being already furnished with from five to eight distinct and concentric circles of longitudinal tubes or sap-vessels, imbedded at regular intervals in its pulp; whereas other biennal roots form only an individual circle each year, and are, consequently, at no time furnished with more than two.

787. Migratory roots depend on a principle similar to the foregoing. If the stem of a descending root happens to be very slender instead of being erect, then the several shoots from above are carried forward in the direction of that procumbency, so that in the course of a few years the plant has actually changed its place by so much as the stem has been converted into a root. This is well exemplified in the genus Lavatera, as an annual in the central parts of Europe, forms a ring of plants instead of a solitary one. In the case of some aquatics, which float about on the surface of the water as they happen to be driven by the winds, the whole plant may be said to be migratory, as in the case of the genus Lemna, and some marine plants.

788. Roots changed to branches and branches to roots. If the stem of a young plum or cherry tree, but particularly of a willow, is taken in the autumn and bent so that one half of the top may be laid in the earth, one half of the root being at the same time taken carefully out, but sheltered at first from the cold and then gradually exposed to it, and the remaining part of the top and root subjected to the same process, in the following year, the branches of the top will become roots, and the ramifications of the root will become branches, protruding leaves, flowers, and fruit in due season.

789. If the stem of a tree planted by a pond or river is so bent in its growth as to come near to the surface of the water and to be occasionally immersed in it, it will sometimes send out from the under surface a multitude of shoots that will descend into the water, and develop themselves in the manner of the fox-tail-root. Sometimes it happens that a stem, instead of assuming the cylindrical form common to the species, assumes a compressed and flattened form similar to the herbage of the cactus as in the fir-tribe, ash, &c.

789. The anomaly of the flattened stem (fig. 58, a) is accounted for by Du Hamel by supposing that an unnatural graft must have taken place in the leaf-bud; and so united shoots that would otherwise have been distinct. Sometimes the stem is disfigured by accidental tumors or bunches projecting from the surface, and forming ultimately what are called knots in the wood. They are very common in the oak and elm, and are produced perhaps by means of some interpenetration in the channel of the sap's movement, by which the vessels become convoluted and swell up into a bunch.

791. But bunches are also to be met with on the stem of herbaceous plants, as on that of the carduus pratensis; of which you will often find a portion near the top swollen out into an egg-shaped or egg-oblung bunch, being from inch to an inch and a half across. If this bunch is cut open in the month of August, it will be found to contain several large and white maggots. It has consequently been occasioned by the puncture of the parent insect depositing its eggs. It does not seem to affect the general health of a vigorous plant, though it might prove seriously injurious to a weak one.

791. Bended stem. Sometimes two or more contiguous stems, extending in the process of their growth till they meet and press against one another, become incorporated at length into one, and form a sort of bundle. This is what may be termed a natural graft, in opposition to an artificial graft, of which
it is the model and prototype. The natural graft is always affected by means of the union of the liber of the respective stems composing it; so that the perfection of the art of grafting consists in applying the liber of the graft and stock together in such a manner as shall most facilitate their incorporation.

793. If the branch of a tree is situated as in the foregoing case of the stem, so as to be partially or periodically immersed in water, it will send out also the same sort of brush-like shoots.

794. Bunches or knots, exhibiting a plexus of young shoots (fig. 59 a) issuing from nearly the same point, crossing in all directions, and finally incorporating together by means of a sort of natural graft, frequently disfigure it. These bunches are frequently to be met with on the branches of the birch-tree, and are known among the peasantry of Scotland by the name of witches' knots. They are occasioned, like the bunches of the stem, by some obstruction in the channel of the sap or proper juice. A peculiar sort of knot or bunch is also often formed on the branches of the dog-rose. The nucleus, which is generally from an inch to an inch and a half in diameter is covered with a long and winged shag, first of a green and then of a purple color, presenting the appearance of a small bunch of moss. (fig. 59 b) It has been occasioned like that of the stem of the thistle, by the puncture of an insect depositing its eggs in the tender shoot; for if it is cut open about the month of August, its contains maggots. These anomalies remind us always of that singular disease in the human species, the Plica polionica.

795. The bud. The regular development of the bud is also often prevented by means of the puncture of insects, and converted into a large globular tumor.

796. The gall tumor is very often effected by a species of Cynips that lance its piercer into the heart of the bud while yet tender, and penetrates with its saw into the very pith; injecting at the same time a drop of the corroding liquor contained in its bag, and then laying its egg. The bud being thus wounded, and the juices corrupted by the injected poison, the circulation is not only impeded, but a fermentation is induced which burns the contiguous parts and changes their color. The extravasated juice flows round the egg, and is there accumulated and converted into a sort of spongy lump which vegetates and augments till it forms what is called a gall. The gall thus formed affords both shelter and nourishment to the young maggot, which, after being converted into a fly, pierces its enclosure and launches into the open air. The most remarkable of such galls are those produced on the oak-tree, and known in this country by the vulgar name of oak-apples. (fig. 59 b) The bud of the willow, particularly salix helix, is apt always to be punctured by insects and converted into a gall. But the conversion is not always complete; and in this case the shoot remains dwarfish, and the leaves, which are now protruded from nearly the same point, assume something of the figure of a rose. Hence it has obtained the common name of the rose-willow. The galls of the salvia pomifera formed in the above manner are said to be of a very pleasant flavor, and are esteemed a great delicacy in eastern countries.

797. The leaves, like the buds, are also frequently chosen for the nidus of insects, and disfigured with galls or excrescences. But the most remarkable gall produced on the leaf, and indeed the most remarkable and important of all galls, is that which is so extremely useful in the arts of dyeing and making ink, the nut-gall of the shops.
798. The nut-gall is generated on the leaf of a species of oak that grows plentifully in the Levant, and is so well known in commerce as to require no particular description. It is occasioned by the puncture of the *Cynips quercusfolii*, which deposits its egg in the substance of the leaf, by making a small perforation on the under surface. Galls and tumors are to be found on the leaves of many plants; and indeed almost all leaves are liable to deformities, giving them a blistered, wrinkled, or curled appearance; and often producing disease.

799. The excess or deficiency of leaves protruded in a group sometimes constitutes the anomaly, as in the case of the trefoils.

800. Sometimes in the natural figure of the leaf itself, as in asparagus officinalis, where they are bristle-shaped; oralsa kali, awl-shaped; and allium cepa, in which they are tubular, tapering to a point. But one of the most remarkable anomalies of figure is that which occurs in the leaves of the genus *Salsola* (fig. 45. b), of which the lower portion is tubular, ascending, and approaching to funnel-shaped, or rather pitcher-shaped reversed, with a flattened and concave limb attached by the one side to the orifice of the tube, and constituting the upper portion of the leaf. Linnæus, who was acquainted with this singularity of structure, supposed that it was an institution of nature, meant for the purpose of furnishing the plant with a supply of water, which it could thus catch and retain in the leaf. But as some species of the genus do not readily admit water notwithstanding their capacity to retain it, this hypothesis is regarded by Sir J. E. Smith as being extremely doubtful, who accordingly offers a different solution, founding on the fact that Sprengel in the *Sphex or Ichneumon* kind, had been observed by one of the gardeners of the botanic garden at Liverpool, to drag several large flies to a leaf of sarracenia, adnuncia, and to force them into the tubular part of it. On examination, the leaf was found to be about half filled in most places by struggling insects; the other leaves were also examined, and were found crammed with dead or drowning flies. The leaves of sarracenia purpurea are said to exhibit also the same phenomena, and seem peculiarly well adapted to entrap and confine flies, by having the margin beset with inverted hairs rendering the escape of such insects as may have accidentally fallen into the watery tube, or are intentionally forced into it, impracticable; so that the patrid exhalation from the dead insects contained in the leaf often offends the nostrils, even in passing near the plant. Hence Sir J. E. Smith infers, that the growth of the plant is perhaps benefited by means of the air evolved by the dead flies which have been introduced into and the leaves are, at least to the torment, and the leaf offend, as a leaf can not be sufficiently thick as the plant may be affected; but cannot be regarded as quite satisfactory till such time as it shall have been shown that the health of the plant is injured when insects are prevented from approaching it.

801. The celebrated nepthys or eyes of noble (fig. 45. c) exhibits also an anomaly similar to that of sarracenia, by holding an ounce or two of a fluid which appears to be secreted from the leaf, and to be intended as a lure to insects, which gain admission either by the spontaneous opening of the lid, or by forcibly raising it themselves. The consequence is this: the opening is filled into the fluid and are drowned, no insect being capable of living in it except a certain small squilla or shrimp, with a protruder back, which, according to Romuls, sometimes crawls in it and can live there. To this phenomenon Sir J. E. Smith applies the same explanation as above, which is of course liable to the same objection.

802. The figure of the leaf, however singular, is generally the same throughout the same individual, except in the case of accidental deformity, and yet there are exceptions even to this rule. For some leaves of a plant are entire while the upper leaves are divided, as occurs in a variety of mountainous plants, such as burnet, saxifrage, anise, coriander; and sometimes the lower leaves are divided while the upper leaves are entire, as in a variety of aquatic, particularly ranunculus aquaticus, in which the lower leaves are capillary and immersed, and the upper leaves flat and circular, floating on the surface of the water. But sometimes the dissimilitude of the leaves is still more remarkable. The Chines makes two leaves alike in form on the whole plant. And lastly, there are some plants, as in the case of the fungi, which are wholly destitute of leaves, and hence called aphyllus; while there are others, as in the case of the fuse, that seem to be wholly leaf.

803. The principal anomaly of the flower, is that by which one of its parts is unduly augmented, to the exclusion or diminution of some of the rest. The flower is then said to be luxuriant, and comprises the three following varieties: the multPLICATE, the full, and the proliferous flower.

804. The multPLICATE flower is sometimes, though rarely, occasioned by an unusual multiplication of the divisions of the corolla, or of the pistil itself, in diathyes, or diaplasties. But the anomaly most generally consists in the undue multiplication of the divisions of the corolla, by the conversion of part of the stamens into petals which is occasionally to be met with both in monopetalous and polypectalous flowers. It occurs but seldom, however, in flowers growing in their natural state and habit, though now and then it has been met with in duplicate flowers.

805. The full flower is generally described to be that in which the divisions of the corolla are so multiplied as to exclude the stamens and pistils wholly by means of their conversion into petals; which conversion is most commonly in effect, in polypetrous flowers, such as the full rose, the poppy, and ranunculus; in monopetrous flowers seldom being found full. This complete metamorphosis is always either the effect of cultivation, or of some concurrence of natural circumstances analogous to it; and is indeed one of the principal objects of the art of the florist; the beauty of the flower, according to general estimation, being then on the height. In the case of stamens are already always converted into petals, whence we should perhaps infer their identity of origin. But the pistil is often converted into a leaf, as may be seen by inspecting the flower of the double-blossomed cherry, which generally protrades from the centre a leaf in full, which may become also by the multiplication of the parts of the nectary, as is sometimes the case in the genus *Aquilegia*, which produces full flowers in three different ways — by the multiplication of the petals to the exclusion of the stamens; by the multiplication of the petals to the exclusion of the stamens; by the multiplication of the petals to the exclusion of the nectaries, by the multiplication of the stamens to the exclusion of the petals, and by the multiplication of the stamens while the proper petals remain. There are also some peculiarities in the manner in which compound flowers become full. Radiated flowers become full sometimes by the multiplication of the floesce of the ray to the exclusion of the floesce of the disk, as in helianthus, anthismus, and centaurea; and sometimes by the multiplication of the floesce of the disk to the exclusion of those of the ray, as in matricaria and bellis.

806. The proliferous flower (fig. 60.) is that out of which another flower or another shoot is produced. It is seldom found but in flowers already full; from the centre of which, that is, from the ovary or pistil, it sometimes happens that a new flower and foot-stalk is produced, if the flower is simple, as in the ranunculus, anemone, and pink; or several flowers and foot-stalks, issuing from the common calix, if the flower is compound, as in the daisy, hawkweed, and marigold; or a new umbel issuing from the centre of the original umbel, if the
flower is umbellate, as in cornus. Sometimes the proliferous issue of the full flower is not itself a flower, but a shoot furnished with leaves, as has been sometimes, though rarely, observed in the case of the anemone and rose. Such are three or four varieties of luxuriant flowers, constituting anomalies of excess; but it sometimes happens that there is also in the flower an anomaly of defect in the absence of one of its parts. Examples of this sort are occasionally to be met with in the flowers of cherianthus cheri, campilina pentagonia, and tussilago anardania, in which the corolla is altogether wanting, though present to the species; and in this case the flower is said to be mutilated. Sometimes the anomaly consists in the situation of the flower, which is generally protruded from the extremity or sides of the branches. But the flower of the ruscus is protruded from the surface of the leaf; or it may consist in the relative situation of the several parts of the flower. In simple flowers the pistil is invariably central with regard to the flower; but in compound flowers the pistils are often situated in the circumference and the stamens in the centre. This seems to be the case also with some monoeccious plants having their flowers on the same peduncle, as in the examples of the carex and arum, in which the stamens are more central than the pistils. Sometimes the anomaly consists in the color of the corolla, which will often deviate even in the same species. The general color of the common cowslip (Primula veris) is a bright yellow; but an individual is occasionally to be met with, though very rarely, in which the limb or expansion of the corolla is purple with a line of yellow around the border. Sometimes the anomaly consists in the time of flowering. The season proper for the flowering of the simple and petals alone is the month of May; but trees of that sort have been known to protrude both buds and blossoms even in the month of November. Some plants, however, blow only in the winter, in the case of the laturenus and arbutus unedo; while others blow only in the night, and refuse to expand their petals to the light of the sun. Such is the case of the cactus grandiflorus, that produces one of the most magnificent of flowers; but blows only in the night; and is hence known also by the appellation of the night-blowing cecereus. Some plants, such as the ferns, algae, and fungi, are altogether destitute of conspicuous flowers; and are hence called Cryptogamous; but in this respect the fig is perhaps the most singular. The flowers of which in other cases uniformly precede the fruit, are in this case concealed within what is generally denominated the fruit; as may be proved by cutting open a green fig (fig. 61. a) by means of a longitudinal section passing through its axis. Great numbers of flowers (b) are then discovered, a sort of cavity in the axis of the fruit; and hence what is called the fruit or fig, in common language, is rather the receptacle of the flower than any thing else. Most plants have their flowers flnished both with stamens and pistils, and are hence hermaphrodites; but there are also many genera that have the stamens in one flower and the pistils in another, both on the same individual; these are denominated Monoeccious plants, and are exemplified in the oak and hazel. Other genera have the flowers with stamens on one plant, and the flowers with pistils on another; these are denominated Dioecious, and are exemplified in the holly and willow. Others have flowers of all the previous kinds on one and the same plant; these are denominated Polygamous, and are exemplified in the genus Atriplex.

807. The fruit. The anomalies of the fruit may affect either its number, figure, color, or appendages. The common hazel-nut produces in general but one kernel in one shell; but in the course of opening up a considerable number, you will now and then meet with one containing two or three kernels in a shell.

This is perhaps best accounted for by supposing, with Du Hamel, that it is the result of an unnatural graft effected in the bud; though some think that the shell does always contain the rudiments of two or more kernels, although it rarely happens that more than one is developed. But if two apples or pears are developed in an incorporated state, which is a case that now and then occurs, it is no doubt best accounted for by the graft of Du Hamel. Sometimes the anomaly consists in the figure of the fruit, which is deformed by tumors or excrescences, in consequence of the bite of insects, or injuries of weather producing warts, moles, or specks. Sometimes it consists in the color, producing green melons and white cucumbers. Sometimes it consists in an appendage of leaves. (fig. 62.)

808. Habit. Some plants, which, when placed in a rich soil, grow to a great height and affect the habit of a tree, are, when placed in a poor soil, converted into dwarf shrubs.

This may be exemplified in the case of the box-tree; and so also in the case of herbaceous plants; as in the monoeccious, which in dry situations is but short and dwarfish, while in moist situations it grows to such a size as to seem to be altogether a different plant. The habit of the plant is sometimes totally altered by means of cultivation; the pyrus sativa, when growing in a wild and uncultivated state, is furnished with strong thorns; but when transferred to a rich and cultivated soil the thorns disappear. This phenomenon was observed by Linnaeus, was regarded as being equivalent to the taming of animals. But this explanation is, like some others of the same great botanist, much more plausible than profound, in place of which Professor Wilkewiow substitutes the following: The thorns protruded in the uncultivated state of the plant, are budded off from the system of nutrition, which when supplied with a sufficiency of nourishment, are converted into leaves and branches.

809. Physical virtues. When plants are removed from their native soil and taken into a state of culture, it alters not only their habit but their physical virtues. Thus the sour grape is rendered sweet, the bitter pear pleasant, the dry apricot pulp, the prickly
SEXUALITY OF VEGETABLES

810. **Duration.** Plants are either annuals, biennials, or perennials, and the species is uniformly of the same class. But it has been found that some plants which are annuals in a cold climate, such as that of Sweden, will become perennials in a hot climate, such as that of the West Indies; this anomaly has been exemplified in tropaeolum, beet-root, and malva arborica: and, on the contrary, some plants, which are perennials in hot climates, are reduced to annuals when transplanted into a cold climate; this has been exemplified in mirabilis and ricinus.

**Sect. VI. Of the Sexuality of Vegetables.**

811. The doctrine that plants are of different sexes, and which constitutes the foundation of the Linnaean system, though but lately established upon the basis of logical induction, is by no means a novel doctrine. It appears to have been entertained even among the original Greeks, from the antiquity of their mode of cultivating figs and palms. Aristotle and Theophrastus maintain the doctrine of the sexuality of vegetables; and Pliny, Dioscorides, and Galen, adopted the division by which plants were then distributed into male and female; but chiefly upon the erroneous principle of habit or aspect, and without any reference to a distinction absolutely sexual. Pliny seems to admit the distinction of sex in all plants whatever, and quotes the case of the palm-tree as exhibiting the most striking example.

812. **Discoveries of the moderns.** Cesalpinus, in the sixteenth century, denominates trees which produce fruit only, females; and trees of the same kind which are barren, males; adding, that the fruit is found to be more abundant and of a better quality where the males grow in the neighbourhood of the females. It is but occasional exhalations from the males dispersing themselves all over the females, and by an operation not to be explained, disposing them to produce more perfect seed. About the middle of the seventeenth century, the doctrine of the sexes of the plants began to assume a more fixed and determinate character. Malpais describes the stamens, anthers, and pollen: the merit of suggesting the use of the latter seems to be between Sir T. Millington, Savilian Professor at Oxford, and the celebrated Dr. Grew. The opinion of Grew was adopted also by Ray. The first example of experiment recorded on this subject is that of Camerarius, professor of botany at Tubingen, who having adopted the opinion of Grew and Ray, though without perhaps regarding their arguments as the best that could be adduced, conceived that the subject might be still further illustrated by means of depriving the plant of its male flowers altogether, or of removing the individuals of a different sex to a distance from one another. Accordingly having set some of the male plants of mimulus, morus, sea mays, and ricinus, stripped of their staminate flowers, or removed the male plant to a great distance from the female, he found that the fruit did not now ripen; the inference from which was, that the generation of plants is analogous to that of animals, and that the stamens of the flowers of the former correspond to the sexual organs of the males of the latter. The great and illustrious Linnaeus, reviewing with his usual sagacity the evidence on which the doctrine rested, and perceiving that it was supported by a multiplicity of the most incontrovertible facts, resolved to devote his labours peculiarly to the investigation of the subject, and to prosecute his enquiries throughout the whole extent of the vegetable kingdom; which great and arduous enterprise he not only undertook but accomplished with a success equal to the unexampled industry with which he pursued it. So that by collecting into one body all the evidence of former discovery or experiment, and by adding much that was original of his own, he found himself at length authoritatively to draw the important conclusion—that no seed is perfected without the previous agency of the pollen; that the doctrine of the sexes of plants is consequently founded in fact.

813. **Proofs from the economy of the aquatics.** Many plants of this class that vegetate for the most part wholly immersed in water, and often at a considerable depth, gradually begin to elevate their stems as the season of flowering advances, when they at last rear their heads above the surface of the water, and present their opening blossoms to the sun, till the petals have begun to fade, when they again gradually sink down to the bottom to ripen and to sow their seeds. This very peculiar economy may be exemplified in the case of rupia maritima, and several species of potamogenon, common in our ponds and ditches; from which we may fairly infer, that the flowers rise thus to the surface merely to give the pollen an opportunity of reaching the stigma uninjured. But the most remarkable example of this kind is that of the valisneria spiralis (fig 63), a plant that grows in the ditches of Italy. The plant is of the class Dicrana, producing its fertile flowers on the extremity of a long and slender stalk twisted spirally like a corkscrew, uncoiling of its own accord, about the time of the opening of the blossom, elevating the flowers to the surface of the water, and leaves them to expand in the open air. The barren flowers are produced in great numbers upon short upright stalks issuing from a different root, from which they detach themselves about the time of the expansion of the female blossom, mounting up like little air bubbles, and suddenly expanding when they reach the surface, where they float about in great numbers among the female blossoms, and often cling to them in clusters so as to cover them entirely; thus bringing the stamens and pistils into immediate contact, and giving the anthers an opportunity of discharging their pollen immediately over the stigma. When this operation has been performed, the plant begins again to resume its original and spiral form, and gradually sinks down, as it gradually rose, to ripen its fruit at the bottom of the water. We have gathered (in 1819) these stalks, in the canals near Padus, upwards of ten feet long.
Sect. VII. Impragnation of the Seed.

814. The stamens and pistils are the male and female organs of vegetable generation, and the pollen is the substance by which the impragnation of the seed is effected; but how is the pollen conveyed to the ovary? And what is the amount of its action?

815. Access of the pollen. When the stamens and pistils are situated near each other, the elastic spring, with which the anther flies open, will generally be sufficient to disperse the pollen, so that part of it must infallibly reach the stigma in such flowers as do not perfect their stamens and pistils at the same time. The pollen is very generally conveyed from the anther to the stigma through the instrumentality of bees and other insects; and in this respect the doctrine of its fertilizing, which, whilst it roves from flower to flower, and rummages the recesses of the corolla, it unintentionally covers its body with pollen, which it conveys to the next flower it visits, and brushes off as it acquired it by rummaging; so that part of it is almost unavoidably deposited on the stigma, and impragnation is thus effected. Nor is this altogether so much a work of random as it at first appears. For it has been observed that even insects, which do not upon the whole confine themselves to one species of flower, will yet very often remain during the whole day upon the species they first alighted on in the morning; hence it is that those plants where the following are directed, whose blossoms are near. Hence also a sort of natural crossing of the breed of plants which might probably otherwise degenerate.

816. Fecundation of the ovary. Admitting that the pollen is conducted to the ovary through the channel of the tubes of the style, how after is the ovary fecundated; or the seed rendered fertile? On this subject naturalists have been much divided; and according to their several opinions have been classed under the respective appellations of ovarists, animalcultists, and epigenists.

817. Ovarist. According to the opinion of the Ovarist, the embryo pre-exists in the ovary, and is fecundated by the agency of the pollen as transmitted to it through the style.

818. According to the theory of the Ovarists, it is held that the embryo is not without peculiar difficulties; for as the embryo is never found to make its appearance till after fecundation, it has been thought that it must necessarily pre-exist in the ovary; from which it is conveyed to the ovary through the medium of the style, and afterwards matured. It is argued upon that the generative power which supposes the pre-existence of animalca in the seminal principle of the male, the animalca being conveyed in coitus to the ovary of the female, where alone they are capable of development.

819. Epigenist. The difficulties inseparable from both these theories, together with the phenomenon of hybrid productions, have given rise also to a third; this is the Theory of the Epigenists, who maintain that the embryo pre-exists neither in the ovary nor pollen, but is generated by the union of the fecundating principles of the male and female organs; the former being the fluid issuing from the pollen when it exudes, and the latter, the fluid issuing from the stigmas of the stamens, to which if the seed is generated from the union of two fecundating principles which form an intermediate offspring, then female plants of the class Dicresta ought occasionally to produce seeds whose offspring shall be Hermaphrodite, or at least Monocious, which was never yet known to happen.

820. Hybrids. Although the arguments of the epigenists are by no means satisfactory, yet it cannot be denied, that hybrid productions partake of the properties both of the male and female from which they spring. This was long ago proved to be the fact by Bradley, and more recently confirmed by the experiments of Knight; as well as happily converted to the advantage of the cultivator.

821. Vegetable crossing. Observing that farmers who rear cattle improve the progeny by means of crossing the breed, Knight argued from analogy, that the same improvement might be introduced into vegetables. His principal object was that of procuring new and improved varieties of the apple and pear to supply the public with more healthy food. But a multitude of experiments of this kind, with regard to the fruit in question, did not keep pace with the ardor of his desire to obtain in formation on the subject, he was induced to institute some tentative experiments upon the common pea,—a plant well suited to his purpose, both from its quickness of growth, and from the many varieties in form, size, and color, which are obtained by the crosses. The cross was guarded from any injury or degradation, and the pease were growing in his garden, which had not recovered its former vigor even when removed to a better soil. Being thus a good subject of experiment, the male organs of a dozen of its immature blossoms were destroyed, and the female organs left entire. When the blossoms had attained their mature state, the pollen of a very large and luxuriant grey pea was introduced into the one half of them, but not into the other. The pods of both grew equally; but the seeds of the half that were unpregnated withered away, without having augmented beyond the size to which they had attained before the blossoms expanded. The seeds of the other half were augmented and matured as in the ordinary process of impragnation; and exhibited no perceptible difference from those of other plants of the same variety; perhaps because the external covering of the seed was furnished entirely by the female. But when they were made to vegetate in the succeeding spring, the effect of the experiment was obvious. The plants rose with great luxuriance, indicating in their stem, leaves, and fruit, the improved and artificial character of the seed; the seeds of the female were of a grey color, but the seeds of the male were of a rich purple. Thus the flowers of this variety with the pollen of others, the color was again changed, and new varieties obtained, superior in every respect to the original on which the experiment was first made, and attaining in some cases to a height of twelve feet. (Quoted from Trans. Roy. Soc. Edin.) The experiments on this subject afford examples of superfertation, a phenomenon, the existence of which has been admitted amongst animals, but of which the proof amongst vegetables is not yet quite satisfactory. Of one species of superfertation he has certainly produced examples; that is, when, by impragnating a white flower with the pollen of a black, a white flower was produced with a black eye. But of the other species of superfertation, in which one seed is supposed to be the joint issue of two males, the example is not quite satisfactory. Such a production is perhaps possible, and further experiments may by ascertained to the fact; but it seems to be a matter of mere curiosity, and not apparently connected with any views of utility.

822. The practicability of improving the species, is rendered strikingly obvious by these experiments; and the ameliorating effect is the same whether by the male or female; as was ascertained by impragnating a finely marked flower with the pollen of the most dimished and unmarked, as well as the contrary. By such means any number of varieties may be obtained, according to the will of the experimenter, amongst which some will no doubt be suited to all soils and situations. Knight's experiments of this kind were extended also to wheat; but not with equal success. For though some very good varieties were obtained, yet they were found not to be permanent. But the success of his experiments on the apple-tree were equal to his hopes. This was indeed his principal object, and no means of obtaining a successful issue were left untried. The plants which were obtained in this case
were found to possess the good qualities of both of the varieties employed, uniting the greatest health and luxuriance with the finest and best-flavoured fruit.

823. Improved varieties of every fruit and vegetable plant may be obtained by means of artificial impregnation. Crossing, as the more eligible of the cases already stated. Whence Knight thinks, that this promising impregnation of species has been intended by nature to take place, and that its purpose for correcting such accidental varieties as arise from seed, and of confining them within narrower limits is at once discerned from the consideration of the variety of methods which nature employs to disperse the pollen, either by the elastic spring of the anthers, the aid of the winds, or the instrumentality of insects. But, although he admits the existence of vegetable hybrids, that is, of varieties obtained from the intermixture of the species of vegetable mules, that is, of varieties obtained from the intermixtures of the species of different genera; in attempting to obtain which he could never succeed, in spite of all his efforts. Hence he suspects that where such varieties have been supposed to take place, the variety is misjudged. It may be in many cases that the idea arises from the consideration of the animal kingdom, why not in the vegetable kingdom? to which it is, perhaps, difficult to give a satisfactory reply. But from the narrow limits within which this intercourse is in all cases circumscribed, it scarcely seems to have been the intention of nature that it should succeed. "(Hort. Trans. L. 364.) that new species may be created both by bees and the agency of man; and the recent experiments of Herbert, Sweet, and others seem to confirm this opinion. Sweet's experience leads him to conclude that the plants of all orders strictly natural may be repeatedly impregnated with success, and as far as it has already, in the nursery-gardens of Meissa Colville, produced many new geraniums and rhododendrons.

824. A singular or anomalous effect of crossing, or extraneous impregnation, is the change sometimes undergone by the seed or fruit which is produced by the blossom impregnated. These effects are not uniform results, but they are of frequent occurrence, and have attracted notice from a very early period. John Turner observes (Hort. Trans. v. 65.) that Theophrastus and Pliny (Theophrast. Hist. Plant. i. l. c. 4.; Plinius Hist. Nat. l. xvii. c. 53.) seem to allude to it, and that the notion was entertained by Bradley, who, in his "New Orchard," after giving directions for fertilizing the bride, observed that the impregnation of the hazel with the pollen of the male, says, "By this knowledge we may alter the property and taste of any fruit, by impregnating the one with the farina of another of the same kind, as, for example, a codlin with a pearmain, which will occasion the codlin so impregnated in time to become a sharper taste, or if the fruit should be fecundated with the dust of the summer kinds, they will decay before their usual time; and it is from this accidental concourse of the farina of one kind with the other, that in an orchard, where there is variety of apples, even the fruit gathered from the same tree differs in its flavor and times of ripening;" and, moreover, the seeds of these apples are generally being changed by that means from their natural qualities, will produce different kinds of fruit, if they are sown. Turner, after quoting several instances, and, among others, one from the Philosophical Transactions concerning the effect which the farina of the blossom has on the fruit of different parts of different trees, remarks, that on the species of trees and the different parts of the blossom impregnated, the fruit will be different, that is to say, some will be sweeter, others more acid, and some will have a peculiar taste; and says, that sometimes the seed is said to be much improved in planting and gardening, and that the fruit will be larger than usual. But the few cases of the kind which have hitherto been related, are principally those of the apple, the plum, and the pear, and from these it may be inferred, that this method of impregnating by crossing, is particularly applicable to those plants which are not so easily propagated by cuttings or seeds; in which case the fruit of the same tree, which has been impregnated by one sort of blossom of another tree, differs in its flavor and ripening from the fruit of the same tree, which has been impregnated by another blossom of the same tree. But it is not yet ascertained whether this varies in different kinds or species of plants, or whether it is more apparent in some than in others; and, in order to determine this point, it will be necessary to collect a great number of cases, and to compare them together.

825. The peculiar changes consequent upon impregnation, whether in the flower, or fruit, may be considered as external and internal.

869. External changes. At the state of the impregnation of the ovary the flower has attained to its ultimate state of perfection, and displayed its utmost beauty of coloring and richness of perfume. But as it is now no longer wanted, so it is no longer provided for in the economy of generation. It then becomes a receptacle, in which the seeds are contained; for the decay of the ovary, if not indicated by the stumps of the petals, and of the calyx, which wither and shrink up, and finally detach themselves from the fruit altogether, except in some particular cases in which one or other of them becomes permanent and falls only with the fruit. The stigma exhibits also similar symptoms of decay and disintegration, and the stamens also, with the processes and floral leaves, are sometimes also affected; and finally the whole plant, at least in the case of annuals, begins to exhibit indications of decay. But while the flower withers and falls, the ovary is advancing to perfection, swelling and augmenting in size, and receiving now all the nutriment by which the decayed parts were formerly supported. Its color begins to assume a deeper and richer tinge; its figure is also often altered, and new parts are even occasionally added—wings, crests, prickles, hooks, bloom, down. The common receptacle of the fruit undergoes also similar changes, becoming sometimes large and succulent, as in the fig and strawberry; and sometimes juiceless and indurated, as in orange and other fruits.

867. Internal changes. If the ovary is cut open as soon as it is first discoverable in the flower, it presents to the eye merely a pulpy and homogeneous mass. But the same ovary, when it shall be fecundated, is found to be divisible into several distinct parts, exhibiting an apparatus of cells, valves, and membranes, constituting the pericarp, and sometimes the external coats of the seed. In this case the umbilical cord is also to be distinguished; but the embryo is not yet visible. It is a mass of cells, and the formation of the vegetable development, and are not at all dependent upon impregnation. But impregnation has no sooner taken place than its influence begins to be visible; the umbilical cord, which was formerly short and distended, is now generally converted into a long and slender thread. Soon after the opening of the seed, the cells of carophyllus aromatics, and netosideros gymniferae, are horizontal; after impregnation they become vertical. Before impregnation the magnolia seeds are acute; after impregnation they become inverted and pendulous. The figure of the seed is often also altered; the seed of Gernert (in the young state) is ovate, and the embryo is included in the seed, as in a bladder; the seed of Lactuca, at first round, becomes ovoid, from oval to round, and from round to kidney-shaped. But all seeds are not brought to maturity, by which the rudiments may exist in the ovary. Lagroia and hasselquistia, produce uniformly the rudiments of two seeds, of which they mature but one. But the rudiments of the second seem to be formed from impregnation, a previous a homogeneous and gelatinous mass, is now converted into an organised body, or embryo. Such are the phenomena, according to the description of Gernert, accompanying or following the impregnation of all flowers producing seeds; exceptions occur where the formation is spurious or incomplete; where the ovary swells, but exhibits no traces of perfect seed within, as often happens in the vine and tamus; or when barren and fertile seeds are intermixed together in the same ovar. This proceeds from some defect either in the quantity or quality of the pollen;
but rather in the quality, as it is not always plants having the most pollen that produce the most seeds. The two stamens of the orchis, and 8000 seeds, and the five stamens of tobacco, and 5000 seeds, while the 50 stamens of bariophyllum, the 250 of thea, and the 80 of the caryophyllus, produce only two or three ovaries.

Sect. IX. The Propagation of the Species.

828. As the life of the vegetable, like that of the animal, is limited to a definite period, and as a continued supply of vegetables is always wanted for the support of animals, what we call art, or nature operating by means of the animal man, has taken care to institute such means as shall secure the multiplying and perpetuating of the species in all possible cases.

829. Equivoical Generation. It was long a vulgar error, countenanced even by the philosophies of the times, that vegetables do often spring up from the accidental mixture of putrid water and earth, or other putrid substances, in the manner of what was called the equivocal generation of animals; or at the very least, that the earth contains the principle of vegetable life in itself, which, in order to be excited to activity, must be exposed to the action of the air. The former alternative of the error has been long ago refuted; the latter has lost its hold, having been also refuted by Malpighi, who proved that the earth produces no plant without the intervention of a seed, or of some other species of vegetable germ deposited in it by nature or by art.

830. Propagation by seeds. When the seed has reached maturity in the due and regular course of its development, it can only be secured to perpetuate the vegetable kingdom, if the seeds are to fall into the soil merely by dropping down from the plant, that the germination, instead of being confined and springing up into distinct plants, would grow up only to putrefy and decay; to prevent which consequence nature has adopted a variety of the most efficacious counter-vances, all tending to the dispersion of the seed. The first means to be mentioned, is that of the elasticity of the pericarp of many fruits, by which it opens when ripe, with a sort of sudden spring, ejecting the seed with violence, and throwing it some considerable distance from the plant. This may be exemplified in a variety of cases; the seeds of oats when ripe are projected from the calyx with such violence, that in a fine and dry day you may even hear them thrown out with a slight and sudden snap in passing through a field that is ripe. The pericarp of the Dorsifera Fergu. (fig. 64 a) is furnished with a sort of peculiar elastic ring (b), intended, as it would appear, for the very purpose of projecting the seeds. The capsules of the oxalis, geranium sanguineum, and fraxinella, discharge their seeds also when ripe with an elastic jerk. But the pericarp of impatiens, which consists of one cell with five valves, exhibits perhaps one of the best examples of this mode of dispersion. If it is accidentally touched when ripe it will immediately burst open, while the valves, coiling themselves up in a spiral form, and springing from the stem, discharge the contained seeds and scatter them all around. The bursting of the pericarp of some species of pines is also worthy of notice. The pericarp, which is a cone, remains on the tree till the summer succeeding that on which it was produced, the scales being still closed. But when the hot weather has commenced and continued for some time, so as to dry the cone thoroughly, the scales open of their own accord, and puffing out the contained seeds; and if a number of them happen to burst together, which is often the case, the noise is such as to be heard at some considerable distance. The twisted awn of the oat (fig. 65 a), or wild oat, as well as that of geranium cicutarium, and some others, seems to have been intended particularly for the purpose of aiding the further dispersion of the seed, after being discharged from the plant or pericarp. This spiral awn or spring, which is beset with a multitude of fine and minute hairs, possesses the property of contracting by means of drought, and of expanding by means of moisture. Hence it remains of necessity in a perpetual state of contraction or dilatation, dependent upon change of weather; from which, as well as from the additional aid of the fine hairs which act as so many baffles, and cling to whatever object they meet, the seed to which it is attached is kept in continual motion till it either germinates or is destroyed. The awn of barley, which is beset with a multitude of little teeth all pointing to its upper extremity, presents also similar phenomena. For when the seed with its awn falls from the ear and lies flat upon the ground, it is necessarily extended in its dimensions by the moisture of the night, and contracted by the drought of the day. But as the teeth prevent it from receding in the direction of the point, it is consequently made to advance in the direction of the base of the seed, which is thus often carried to the distance of many feet from the stalk on which it grew. If any one is yet sceptical with regard to the travelling capacity of the awn, let him only introduce an awn of barley with the seed uppermost between his coat and shirt sleeve at the wrist, when he walks out in the morning, and by the time he returns to breakfast, if he has walked to any great distance, he will find it up at his arm-pit. This journey has been effected by means of the continued motion of the arm, and consequently of the teeth of the awn acting as feet to carry it forward.

831. Dispersion of seed. If seeds were to fall into the soil merely by dropping down from the plant, the germination, instead of being confined and springing up into distinct plants, would grow up only to putrefy and decay; to prevent which consequence nature has adopted a variety of the most efficacious counter-vances, all tending to the dispersion of the seed. The first means to be mentioned, is that of the elasticity of the pericarp of many fruits, by which it opens when ripe, with a sort of sudden spring, ejecting the seed with violence, and throwing it some considerable distance from the plant. This may be exemplified in a variety of cases; the seeds of oats when ripe are projected from the calyx with such violence, that in a fine and dry day you may even hear them thrown out with a slight and sudden snap in passing through a field that is ripe. The pericarp of the Dorsifera Fergu. (fig. 64 a) is furnished with a sort of peculiar elastic ring (b), intended, as it would appear, for the very purpose of projecting the seeds. The capsules of the oxalis, geranium sanguineum, and fraxinella, discharge their seeds also when ripe with an elastic jerk. But the pericarp of impatiens, which consists of one cell with five valves, exhibits perhaps one of the best examples of this mode of dispersion. If it is accidentally touched when ripe it will immediately burst open, while the valves, coiling themselves up in a spiral form, and springing from the stem, discharge the contained seeds and scatter them all around. The bursting of the pericarp of some species of pines is also worthy of notice. The pericarp, which is a cone, remains on the tree till the summer succeeding that on which it was produced, the scales being still closed. But when the hot weather has commenced and continued for some time, so as to dry the cone thoroughly, the scales open of their own accord, and puffing out the contained seeds; and if a number of them happen to burst together, which is often the case, the noise is such as to be heard at some considerable distance. The twisted awn of the oat (fig. 65 a), or wild oat, as well as that of geranium cicutarium, and some others, seems to have been intended particularly for the purpose of aiding the further dispersion of the seed, after being discharged from the plant or pericarp. This spiral awn or spring, which is beset with a multitude of fine and minute hairs, possesses the property of contracting by means of drought, and of expanding by means of moisture. Hence it remains in a perpetual state of contraction or dilatation, dependent upon change of weather; from which, as well as from the additional aid of the fine hairs which act as so many baffles, and cling to whatever object they meet, the seed to which it is attached is kept in continual motion till it either germinates or is destroyed. The awn of barley, which is beset with a multitude of little teeth all pointing to its upper extremity, presents also similar phenomena. For when the seed with its awn falls from the ear and lies flat upon the ground, it is necessarily extended in its dimensions by the moisture of the night, and contracted by the drought of the day. But as the teeth prevent it from receding in the direction of the point, it is consequently made to advance in the direction of the base of the seed, which is thus often carried to the distance of many feet from the stalk on which it grew. If any one is yet sceptical with regard to the travelling capacity of the awn, let him only introduce an awn of barley with the seed uppermost between his coat and shirt sleeve at the wrist, when he walks out in the morning, and by the time he returns to breakfast, if he has walked to any great distance, he will find it up at his arm-pit. This journey has been effected by means of the continued motion of the arm, and consequently of the teeth of the awn acting as feet to carry it forward.

832. Where distance of dispersion is required, nature is
also furnished with a resource. One of the most common modes by which seeds are conveyed to a distance from their place of growth is that of the instrumentality of animals. Many seeds are thus carried to a distance from their place of growth merely by their attaching themselves to the bodies of such animals as wander over the earth, or even to come, as it were, and call for them; with which one part or other of the fructification is often furnished serving as the medium of attachment, and the seed being thus carried about with the animal till it is again detached by some accidental cause, and at last be dispersed. Sometimes the seeds are thus conveyed in the fur, the feathers, or the beaks of birds, or even sometimes, as in the case with the hooks or prickles are attached to the seed itself; or in the case of galium aparine and others, in which they are attached to the pericarp; or in the case of the thistle and the burdock, in which they are attached to the general calyx. Many seeds are dispersed by animals in consequence of their pericarps being used as forage, and thus, as it were, in the case with the berries of the drupe, as cherries, sloes, and haws, which birds often carry away till they meet with some convenient place for devouring the pulpy pericarp, and then drop the stone into the soil. And so also fruit is dispersed that has been hoarded for the winter, though not by the seeds itself, as in the case of the nuts boiled, which are often dispossessed by some other animal, that not caring for the hoard scatters and disposes of it. Sometimes the hoard is deposited in the ground itself, in which case part of it is generally found to take root and spring up into plants. Though it has been observed that the ground-squirrel often deprives the kernels of their pericarps, it has also been observed, in the case with other seeds in the holes of fence-posts, which being either, forgot or accidentally thrust out, fall ultimately into the earth and germinate. But sometimes the seed is even taken into the stomach of the animal, being passed through of the soil, and thus giving rise that the seed of many species of berry, such as the mistletoe, which the thrush swallows and afterwards deposits upon the boughs of such trees as it may happen to alight upon. The seeds of the Loranthus americanus, another parasitical plant, are said to be deposited in like manner on the branches of the coccoloba grandiflora, and other leafy trees; as also the seeds of physocala decandra, the berries of which are eaten by the robin, thrush, and wild pigeon. And so also the seeds of currants or roans are sometimes deposited, after having been swallowed by blackbirds or other birds, as may be seen by observing a currant-bush or young roan-tree growing out of the clump of the elder tree, in the wood which may have lain too long to have been little dust collected by way of soil; or where a natural graft may have been effected by the insinuation of the radicle into some chink or cleft. It seems indeed surprising that any seeds should be able to resist the heat and digestive action of the stomach of animals; but it is undoubtedly the case that the seeds of the pignut hellebore, which have been observed to this country, are said to have generally refused to vegetate till after undergoing this process, and it is known that some seeds will bear a still greater degree of heat without any injury. Spallanzani mentions some seeds that germinated after having been boiled in water, or put into the stomach of the stork and other birds, and exposed to a degree of heat measuring 239° of Fahrenheit. In addition to the instrumentality of brute animals in the dispersion of the seed might be added also, that of men, who, for purposes of utility or of ornament, not only transfers to his native soil seeds indigenous to the most distant regions, but sows and cultivates plants which are not indigenous.

833. The agency of winds is one of the most effective modes of dispersion instituted by nature. Some seeds are fitted for this mode of dispersion from their extreme minuteness, such as those of the mosses, lichens, and fungi, which float invisibly on the air, and vegetate wherever they happen to meet with a suitable soil. Others are fitted for it by means of an attached wing, as in the case of the fire-tree and liriodendron tulipifera, so that the seed, in falling from the cone or capsule, is immediately caught by the wind, and carried to a distance. Others are peculiarly fitted for it by means of their being furnished with an aigrette, or a stream of dust, or cleft shell, such as Drasophila; the down of which is so large and light in proportion to the seed it supports, that it is wafted on the most gentle breeze, and often seen floating through the atmosphere in great abundance at the time the seed is ripe. Some have a tail, as in elma vita alba. Others are fitted for this mode of dispersion by means of their only falling into the pericarp, which is also wafted along with them, as in the case of staphylea trifolia, the inflated capsule of which seems as if obviously intended thus to aid the dispersion of the contained seed by its exposing to the wind a large and distended surface with but little weight. And so also in the case of the maple, elm, and ash, the capsules of which are furnished, like some seeds, with a membranous wing, which when they separate from the plant the wind immediately lays hold of and drives before it.

834. The instrumentality of streams, rivers, and currents of the ocean, is a further means adopted by nature in the distribution of seeds. The seeds of many aquatic plants, by floating down the river or the valley the seeds which may accidentally fall into it, or which it may happen to sweep from its banks when it suddenly overflows them. The broad and majestic river, winding along the extensive plain, and traversing the continents of the world, conveys to the distance of many hundreds of miles, the seeds of many kinds of plants, which have colonized the shores of the Baltic are visited by seeds which grew in the interior of Germany, and the western shores of the Atlantic by seeds that have been generated in the interior of America. But fruits indigenous to America and the West Indies have sometimes been found to be carried along by the current of the ocean of the western coast of Europe. The seeds of many garden vegetables, as beans, dolichos pruriens, guillardina bondue, and anakardium occidentale, or cashew-nut, have been thus known to be driven across the Atlantic to a distance of upwards of 2000 miles; and although the fruits now added as examples are not such as could vegetate on the coast on which they were thrown, owing to soil or climate, yet it must be believed that fruits may have been often thus transported to climates or countries favorable to their vegetation.

835. Propagation by seeds. Though plants are for the most part propagated by means of seeds, yet many of them are propagated also by means of germs; that is, bulbs and buds. The caulinar bulb is often the means of the propagation of the species: it generally appears in the axil of the leaves, as in dentaria bulbifera and lilium bulbiferum; or between the spires of their umbels, as in allium canadense; in the midst of the spike of flowers, as in polygonum viviparum and poa alpina. As plants of the last kind are in some places common, it has been customary to make use of nature to secure the propagation of the species in situations where the seed may fail to ripen. The bud, though it does not spontaneously detach itself from the plant and form a new individual, will yet sometimes strike root and develop its parts if carefully separated by art and planted in the earth, and this is to be understood of the leaf-bud, only, for the flower-bud, according to Mirebel, if so treated, always perishes.

836. Propagation by the leaves. The species may sometimes be propagated even by means of the leaves; as in the aloe, some species of arum, and the species of mimosa. The leaves have converted into new plants, by virtue, no doubt, of some latent gem contained in them. The fungi and lichens, according to Gartner, are all genniferous, having no sexual organs, and no pollen impregnating a germ. In the genus Lycoperdon, the gelatinous substance that pervades the cellular tissue is covered by a black and somewhat hairy powder, but the fluid contents of the plant, which has been converted into a proliferous powder also; and in the agarics, hyphum, and boletus, vesicles containing sporeiferous particles are formed within the lamina, pores, or tubes. Hedwig, on the contrary, ascribes to the fungi a sexual apparatus, and maintains that the pollen is lodged in the volva. But here it is to be recollected, as in the case of the suctoria and lichens, that all fungi are not furnished with a volva,
and consequently not furnished with pollen. The confervae and ulcer, together with the genera Elasia and Riccia, are also, according to Girtner, propagated only by gems; while marchantia, anthoceros, Jungermannia, and Lyceperdon, are said to be propagated both by gems and seeds.

838. Runners are young shoots issuing from the collar or summit of the root, and creeping along the surface of the soil; but producing a new root and leaves at the extremity, and forming a new individual, by the decay of the connecting link, as in the strawberry.

839. Slips. The process of raising perennials by slips is well known to gardeners, and should perhaps be regarded as an extension of the old plant, rather than as the generation of a new one; though it serves the purpose of the cultivator equally well as a plant raised from seed, with the additional advantage of bearing fruit much sooner. But how is the root generated which the slip thus produces? If the trunk of a tree is lopped, and all its existing buds destroyed, then there will be protruded from between the wood and bark a sort of protuberant lip or ring formed from the proper juice, and from which there will spring a number of young shoots. The formation of the root in the case of the slip is effected in the same manner, the moisture of the soil encouraging the protrusion of buds at and near the section; and the bud that would have been converted into a branch above ground is converted into a root below.

840. Layers. The mode of propagation by layers is practised upon trees that are delicate, and which cannot readily be propagated by means of slips; in which case the root is generated nearly as in the former case, the soil stimulating the protrusion of buds which are converted into roots. In many plants, such as the currant and laurel, this is altogether a natural process, effected by the spontaneous bending down of a branch to the surface of the soil.

841. Suckers or off-sets. Many plants protrude annually from the collar a number of young shoots, encircling the principal stem and depriving it of a portion of its nourishment, as in the case of most fruit-trees. Others send out a horizontal root, from which there at last issues a bud that ascends above the soil and is converted into a little stem, as in the case of the elm-tree and syringa. Others send out a horizontal shoot from the collar or its neighbourhood; or a shoot that ultimately bends down by its own weight till it reaches the ground, in which it strikes root and again sends up a stem as in the currant-bush and laurel. The two former are called suckers or off-sets, though the term off-set should perhaps be restricted to the young bulbs that issue and detach themselves annually from bulbous roots. The latter is not designated by any particular name, but may be regarded as a sort of natural layer, resembling also, in some respects, the runner; from which, however, it is distinguished in that it never detaches itself spontaneously from the parent plant, as is the case also with the two former. But if either of them is artificially detached, together with a portion of root or a slice of the collar adhering to it, it will now bear transplanting, and will constitute a distinct plant.

842. Grafting and budding. The species is also often propagated, or at least the variety is multiplied, by means of grafting, which is an artificial application of a portion of the shoot or root of one tree or plant to the stem, shoot, branch, or root of another, so that the two shall coalesce together and form but one plant. The shoot which is to form the summit of the new individual is called the scion; the stem to which it is affixed is called the stock; and the operation, when effected, the graft. As the graft is merely an extension of the parent plant from which the scion came, and not properly speaking a new individual, so it is found to be the best method of propagating approved varieties of fruit-trees without any danger of altering the quality of the fruit, which is always apt to be incurred in propagating from seed, but never in propagating from the scion. The scion will also bear fruit much sooner than the tree that is raised from seed; and, if effected on a proper stock, will be much more hardy and vigorous than if left on the parent plant. And hence the great utility of grafting in the practice of gardening. Till lately, grafting was confined to the ligureous plants, but it is now successfully practised on the roots and shoots of herbaceous vegetables; and the dahlia is grafted by the root; the melon on the gourd; the love-apple on the potatoe; the cauliflower on the cabbage, &c. by the shoot. A very ingenious tract has been published on this subject, entitled, Essai sur la Greffe de l'herbe des plantes et des arbres, par Monsr. Le Baron de Tschowly, Bourgeois de Glaris. Paris, 1819.

Sect. X. Causes limiting the Propagation of the Species.

843. Though plants are controlled chiefly by animals, yet they also control one another. From the various sources of vegetable reproduction, but particularly from the fertility and dispersion of the seed, the earth would soon be overrun with plants of the most prolific species, and converted again into a desert, if it were not that nature has set bounds to their propagation by subjecting them to the control of man, and to the depredations of the great mass of animals; as well as in confining the germination of their seeds to certain and peculiar habitations arising from soil, climate, altitude, and other circumstances.
In order to form an idea of the manner in which these act upon vegetation; imagine that every year an enormous quantity of seeds, produced by the existing vegetables, are spread over the surface of the globe, by the winds and other causes already mentioned, all of these seeds which fall in places suitable for their vegetation, and are not destroyed by animals, germinate and produce plants; then among these plants, the strongest, and largest, and those to which the soil is best suited, develop themselves in number and magnitude so as to choke the others. Such is the general progress of nature, and among plants, as among animals, the strong flourish at the expense of the weak. These causes have operated for such a length of time, that the greater number of species are now fixed and considered as belonging to certain soils, situations, and climates, beyond which they seldom propagate themselves, otherwise than by the hands of man.

Sect. XI. Evidence and Character of Vegetable Vitality.

844. The power of counteracting the laws of chemical affinity is reckoned the best and most satisfactory evidence of the presence and agency of a vital principle as inherent in any subject. This principle, which seems first to have been instituted by Humboldt, is obviously applicable to the case of animals, as is proved by the process of the digestion of the food, and its conversion into chyle and blood; as well as from the various secretions and excretions effecting by the several organs, and effecting the growth and development of the individual, in direct opposition to the acknowledged laws of chemical affinity, which, as soon as the vital principle is extinct, begin immediately to give indication of their action in the incipient symptoms of the putrefaction of the dead body. But the rule is also applicable to the case of vegetables, as is proved by the intro-susception, digestion, and assimilation of the food necessary to their development; all indicating the agency of a principle capable of counteracting the laws of chemical affinity; which, at the period of what is usually called the death of the plant, begin also immediately to act, and to give evidence of their action in the incipient symptoms of the putrefaction of the vegetable.

Vegetables are therefore obviously endowed with a species of vitality. But admitting the presence and agency of a vital principle inherent in the vegetable subject, what are the peculiar properties by which this principle is characterised?

845. Excitability. One of the most distinguishable properties of the vital principle of vegetables is that of its excitability, or capacity of being acted upon by the application of natural stimuli, impelling individual parts in a new direction. Bonnet has given it the name of being subject to "energetization."

846. The stimulating influence of light upon the vital principle of the plant is discoverable, whether in the stem, leaf, or flower. The direction of the stem is influenced by the action of light, as well as the color of its leaves. Distance from direct rays of light or weak light produces etiolation, and its antagonism, branching. The luxuriance of branches depends on the presence and action of light, as is particularly observable in the case of hot-house plants, the branches of which are not so conspicuously directed, either to the fly in quest of heat, or to the door or open sash in quest of air, as to the sun in quest of light. Hence also the branches of plants are often more luxuriant on the south than on the north side; or at least on the side that is best exposed to light. The position of the leaf is also strongly affected by the action of light to which it uniformly turns its upper surface. This may be readily perceived in the case of trees trained to a wall, from which the upper surface of the leaf is by constant turning turned to the south, and on a north wall turns itself north. And if the upper surface of the leaf is forcibly turned towards the wall and confined in that position for a length of time, it will soon resume its primitive position upon regaining its liberty, but particularly if the atmosphere is clear. The leaves of the mallows are said to exhibit but slight indications of this action; as also those of the mistletoe, which are equally susceptible on both sides. It had been conjectured that these effects are partly attributable to the agency of heat; and to try the value of the conjecture, Bonnet placed some plants of the airplex in a stove heated to 23° of Reaumur. Yet the stems were not inclined to the side from which the greatest degree of heat came; but to a small opening in the stores. Heat then does not seem to exert any perceptible influence in the production of the above effects. Does moisture? Bonnet found that the leaves of the vine exhibited the same phenomenon when immersed in water, as when left in the open air. Whence it seems probable that light is the sole agent in the production of the effects in question.

But as light produces such effects upon the leaves, so darkness or the absence of light produces an effect quite the contrary; for it is known that the leaves of many plants assume a very different position in the night from what they have in the day. This is particularly the case with winged leaves, which, though fully expanded during the day, begin to droop and bend down about sunset and during the fall of the evening dew, till they meet together on the inferior side of the leaf-stalk, the terminal lobe, if the leaf is furnished with one, folding itself back till it reaches the first pair; or the two side lobes, if the leaf is trifoliate. So also the leaves of the clover; and of the bean, which are not entirely closed down during the night, and those of mimosa pudica fold themselves up along the common foot-stalk so as to overlap one another. Linnaeus has designated the above phenomenon by the application of The Slumber of Plants. The power is also evident from the expansion of the action of light. Many plants do not fully expand their petals except when the sun shines; and hence alternately open them during the day and shut them up during the night. This may be exemplified in the case of papilionaceous flowers in general, which spread out their wings in fine weather to admit the rays of the sun, and again fold them in case of rain. It may be exemplified in the case of corydalis, which is one of that of the dandelion and hawkweed. But the most singular case of this kind is perhaps that of the lotus of the Euphrates, as described by Theophrastus, which he represents as rearing and expanding its blossoms by day, closing and sinking down beneath the surface of the water by night so as to be beyond the grasp of the hand, and again rising up in the morning to present its expanded blossom to the sun. The same phenomenon is related also by Pliny. But although many plants open their flowers in the morning and shut them again in the evening, yet all flowers do not open and shut at the same time. Plants have their hours as to time, once in the course of the day: hence the daily opening and shutting of the flower has been denominated by botanists The Horologium Flora. Flowers requiring but a slight application of stimulus open early in the morning, while others requiring more or less stimulus close later. Some do not open till noon, and some, whose extreme delicacy cannot bear the action of light at all, open only at night, such as theactus grandiflora, or night-blowing
cereus. But it seems somewhat doubtful whether or not light is the sole agent in the present case; for it has been observed that equatorial flowers open always at the same hour, and that tropical flowers change their opening according to the length of the day. The length of the day has been the determining agent in the opening of flowers of plants that are removed from a warmer to a colder climate expand at a later hour in the latter. A flower that opens at six o'clock in the morning at Senegal, will not open in France or England the same hour. A flower that opens at ten o'clock in a place open in France or England till noon or later, and in Senegal it will not open at all. And a flower that does not open till noon or later at Senegal, will not open at all in France or England. This seems as if heat or its absence were also an agent in the opening and shutting of flowers; though the opening of such flowers is precisely either to light or heat or both. But the length of time of some flowers depends not so much on the action of the stimulus of light as on the existing state of the atmosphere, and hence their opening or shutting betokens change. If the Siberian sow-thistle shuts at night, the ensuing day will be fine; and if it opens, it will be cloudy and rainy. If the African marel

...
in opening in North America than in the same latitudes in Europe, because the surface of the earth is higher, or the winters more severe.

850. Maturation of the fruit. Plants exhibit as much diversity in the warmth and length of time necessary to mature their fruit as in their frondescence and flowering; but the plant that flowers the soonest, does not always ripen its fruit the soonest. The hazel-tree, which blows in February, does not ripen its fruit till autumn; while the cherry, that does not blow till May, ripens its fruit in June. It may be regarded, however, as the general rule, that if a plant blows in spring it ripens its fruit in summer, as in the case of the currant and gooseberry; if it blows in summer it ripens its fruit in autumn, as in the case of the vine; and if it blows in autumn it ripens its fruit in the winter. But the meadow-saffron, which blows in the autumn, does not ripen its fruit till the succeeding spring.

851. Such are the primary facts on which a Calendarium Floræ, should be founded. They have not hitherto been very minutely attended to by botanists; and perhaps their importance is not quite so much as has been generally supposed; but they are at any rate sufficiently striking to have attracted the notice even of savages. Some tribes of American Indians act upon the very principle suggested by Linnaeus, and plant their corn when the wild plum blooms, or when the leaves of the oak are about as large as a squirrel's ears. The names of some of their months are also designated from the state of vegetation. One is called the budding month, and another the flowering month; one the strawberry month, and another the mulberry month; and the autumn is designated by a term signifying the fall of the leaf. Thus the proposed nomenclature of the French for the months and seasons is founded in nature as well as in reason.

852. Cold. As the elevation of temperature induced by the heat of summer is essential to the full exertion of the energies of the vital principle, so the depression of temperature consequent upon the colds of winter has been thought to suspend the exertion of the vital energies altogether. But this opinion is evidently founded on a mistake, as is proved by the example of such plants as protrude their leaves and flowers in the winter season only, such as many of the mosses; as well as by the dissection of the yet unfolded buds at different periods of the winter, even in the case of such plants as protrude their leaves and blossoms in the spring and summer, and in which, it has been already shown, there is a regular, gradual, and incipient development of parts, from the time of the bud's first appearance till its ultimate opening in the spring. The sap, it is true, flows much less freely, but is not wholly stopped. Du Hamel planted some young trees in the autumn, cutting off all the smaller fibres of the root, with a view to watch the progress of the formation of new ones. At the end of every fortnight he had the plants taken up and examined with all possible care to prevent injuring them, and found that, when it did not actually freeze, new roots were always uniformly developed.

853. Energies of life in plants like the process of respiration in animals. Hence it follows, that even during the period of winter, when vegetation seems totally at a stand, the tree being stripped of its foliage, and the herb apparently withering in the frozen blast, still the energies of vital life are exerted; and still the vital principle is at work, carrying on in the interior of the plant, concealed from human view, and sheltered from the piercing frosts, operations necessary to the preservation of vegetable life, or protrusion of future parts; though it requires the returning warmth of spring to give that degree of velocity to the juices which shall render their motion cognizable to man, as well as that expression to the whole plant which is the most evident token of life: in the same manner as the processes of respiration, digestion, and the circulation of the blood are carried on in the animal subject even while asleep; though the most obvious indications of animal life are the motions of the animal when awake. Heat then acts as a powerful stimulus to the operations of the vital principle, accelerating the motion of the sap, and consequent development of parts; as is evident from the sap's beginning to flow much more copiously as the warmth of spring advances, as well as from the possibility of anticipating the natural period of their development by forcing them in a hot-house. But it is known that excessive heat impedes the progress of vegetation as well as excessive cold; both extremes being equally prejudicial. And hence the sap flows more copiously in the spring and autumn, than in either the summer or winter; as may readily be seen by watching the progress of the growth of the annual shoot, which, after having been rapidly protruded in the spring, remains for a while stationary during the great heat of the summer, but is again elongated during the more moderate temperature of autumn.

854. Stimulurity. There are also several substances which have been found to operate as stimulants to the agency of the vital principle when artificially dissolved in water, and applied to the root or branch. Oxygenated muriatic acid has been already mentioned: and the vegetation of the bulbs of the hyacinth and narcissus is accelerated by means of the application of a solution of nitre. Dr. Barton, of Philadelphia, found that a decaying branch of liriodendron tulipifera, and a faded flower of the yellow iris, recovered and continued long fresh when put into water impregnated with camphor; though flowers and branches, in all respects similar, did not recover when put into common water.
855. **Irritability.** Plants are not only susceptible of the action of the natural stimuli of light and heat, exciting them gradually to the exercise of the functions of their different organs in the regular progress of vegetation; they are susceptible also of the action of a variety of accidental or artificial stimuli, from the application of which they are found to give indications of being endowed also with a property similar to what we call irritability in the animal system. This property is well exemplified in the genus *Minosa*; but particularly in that species known by the name of the *Sensitive Plant*; and the *dionaea muscipula* and *drosera*. But sometimes the irritability resides in the flower, and has its seat either in the stamens or style. The former case is exemplified in the flower of the berberry and cactus tuna, and the latter in stylidium glandulosum.

856. **Sensation.** From the facts adduced in the preceding sections, it is evident that plants are endowed with a capacity of being acted upon by the application of stimuli, whether natural or artificial, indicating the existence of a vital principle, and forming one of the most prominent features of its character. But besides this obvious and acknowledged property, it has been thought by some phytologists that plants are endowed also with a species of *sensation*. Sir J. E. Smith seems rather to hope that the doctrine may be true, than to think it so.

857. **Instinct.** There is also a variety of phenomena exhibited throughout the extent of the vegetable kingdom, some of which are common to plants in general, and some peculiar to certain species, that have been thought by several botanical writers to exhibit indications, not merely of sensation, but of *instinct*. The tendency of plants to incline their stem and to turn the upper surface of the leaves to the light, the direction which the extreme fibres of the root will often take to reach the best nourishment, the folding up of the flower on the approach of rain, the rising and falling of the water-lily, and the peculiar and invariable direction assumed by the twining stem in ascending its prop, are among the phenomena that have been attributed to instinct. Keith has endeavoured *(Lin. Trans. xi. p. 11.)* to establish the doctrine of the existence and agency of an instinctive principle in the plant, upon the ground of the direction invariably assumed by the radicle and plumelet respectively, in the germination of the seed.

858. **Definition of the plant.** But if vegetables are living beings endowed with sensation and instinct, or any thing approaching to it, so as to give them a resemblance to animals, how are we certainly to distinguish the plant from the animal? At the extremes of the two kingdoms the distinction is easy; the more perfect animals can never be mistaken for plants, nor the more perfect plants for animals, but at the mean, where the two kingdoms may be supposed to unite, the shades of discrimination are so very faint or evanescent that of some individual productions it is almost impossible to say to which of the kingdoms they belong. Hence it is that substances which have at one time been classed among plants, have at another time been classed among animals; and there are substances to be met with whose place has not yet been satisfactorily determined. Of these I may exemplify the genus *Corallina* *(fig. 66.)*, which Linnaeus placed among animals, but which Gærtner places among plants. Linnaeus, Bonnet, Hedwig, and Mirbel, have each given particular definitions. According to Keith, a vegetable is an organised and living substance springing from a seed or gem, which it again produces; and effecting the development of its parts by means of the intro-susception and assimilation of unorganised substances, which it derives from the atmosphere or the soil in which it grows. The definition of the animal is the counterpart: an animal is an organised and living being proceeding from an egg or embryo, which it again produces; and effecting the development of its parts by means of the intro-susception of organised substances or their products. For all practical purposes, perhaps plants may be distinguished...
from animals with sufficient accuracy by means of the trial of burning; as animal substances in a state of ignition exhale a strong and phosphoric odor, which vegetable substances do not.

**VEGETABLE PATHOLOGY.**

**CHAP. IX.**

Vegetable Pathology, or the Diseases and Casualties of Vegetable Life.

859. As plants are, like animals, organised and living beings, they are, like animals also, liable to such accidental injuries and disorders as may affect the health and vigor, or occasion the death of the individual. These are wounds, accidents, diseases, and natural decay.

**SECT. I. Wounds and Accidents.**

860. A wound is a forcible separation of the solid parts of the plant effected by means of some external cause, intentional or accidental.

851. Incisions are sometimes necessary to the health of the tree, in the same manner perhaps as bleeding is necessary to the health of the animal. The trunk of the plum and cherry-tree seldom expand freely till a longitudinal incision has been made in the bark; and hence this operation is often practised by gardeners. If the incision affects the epidermis only it heals up without leaving any scar; if it penetrates into the interior of the bark, it heals up only by means of leaving a scar; if it penetrates into the wood, the wound in the wood itself never heals up completely, but new wood and bark are formed above it as before.

852. Boring is an operation by which trees are often wounded for the purpose of making them part with their sap, or deaden by the bird, to facilitate orpherical the inner side of the trunk of the tree, or rather slanting hole is bored in them with a wamme, so as to penetrate an inch or two into the wood, from this the sap flows copiously; and though a number of holes is often bored in the same trunk, the health of the tree is not very materially affected. For trees will continue to perform their functions for many years; and the hole, if not very large, will close up again like the deep incision, not by the union of the broken fibres of the wood, but by the formation of new bark and wood projecting beyond the edge of the orifice, and finally shutting it up altogether.

853. Girdling is an operation to which trees in North America are often subjected when the farmer wishes to clear his land of timber. It consists in making parallel and horizontal incisions with an axe into the trunk of a tree, and carrying them quite round the stem so as to penetrate through the albumen, and then to scoop out the intervening portion. If this operation is performed early in the spring, and before the commencement of the bloosoming season, the tree rarely survives it; though some trees that are peculiarly tenacious of life, such as acer saccharinum and nyssa integrifolia, have been known to survive it a considerable length of time.

854. Squirt. If a tree is bent so as to fracture part only of the cortical and woody fibres, and the stem or branch but small, the parts will again unite by being put back into their natural position, and well propped up. Especially cure may be expected to succeed if the fracture happens in the spring; but it will not succeed if the fracture is accompanied with contusion, or if the stem or branch is large; and even where it succeeds does the woody fibres do not contribute to the union, but the granular and herbaceous substance only which exudes from between the wood and liser, insinuating itself into all interstices and finally becoming indurated into wood.

855. Pruning. Wounds are necessarily inflicted by the gardener or forester in the pruning or lopping off the superfluous branches, but this is seldom attended with any bad effects to the health of the tree, if done by a skilful practitioner: indeed no further art is required merely for the protection of the tree beyond that of cutting the branch through in a sloping direction so as to prevent the rain from lodging. In this case the wound soon closes up by the induration of the exposed surface of the section, and by the protrusion of a granular substance, forming a sort of circular lip between the wood and bark; and hence the branch is never elongated by the growth of the same vessels that have been cut, but by the protrusion of new buds near the point of section.

856. Felling. In the operation of grafting there is a wound both of the stock and graft; which are united, not by the immediate adhesion of the surfaces of the two sections, but by means of a granular and herbaceous substance exuding from between the wood and bark, and insinuating itself as a sort of cement into all open spaces: new wood is finally formed within it, and the union is complete.

857. Felting is the operation of cutting down trees close to the ground, which certain species will survive, if the stump is protected from the injuries of animals, and the root fresh and vigorous. In this case the fibres of the wood are never again regenerated, but a lip is formed in the case of pruning; and that springing up into new shoots, are protruded near the section; so that from the old shoot, ten, twelve, or even twenty new stems may issue according to its size and vigor. The stools of the oak and ash-tree will furnish good examples; but there are some trees, such as the fir, that never send out any shoots after the operation of felling.

858. If buds are destroyed in the course of the winter, or in the early part of the spring, many plants will again generate new buds that will develop their parts as the others would have done, except that they never contain blossom or fruit. Du Hamel thought these buds sprang from pre-organised gerns which he conceived to be dispersed throughout the whole of the plant, but right since he has discovered the true source of the regeneration of buds, in the proper juice that is lodged in the albumen. Buds thus regenerated never contain or produce either flower or fruit. Perhaps because the fruit-bud requires more time to develop its parts, or a peculiar and higher degree of elaboration, and that this has to this operation is only the effect of a great effort of the vital principle for the preservation of the individual, and one of those wonderful resources to which nature always knows how to resort when the vital principle is in danger. But though such buds do not produce flowers directly, as in the case of plants that bear their blossoms on new shoots, yet the reproductive buds, which produce blossoms and fruit the same season, as in the case of cutting down an old vine, or pruning the rose.

859. Sometimes the leaves of a tree are destroyed partially or totally as soon as they are protruded from the bud or in the fall in the case of deciduous trees; by the hasty consumption of the leaves, or because the leaf is injured in the season, the new leaves will again protrude without subsequent shoots. Some trees will bear to be stripped even more than once in a season, as is the case with the mulberry-tree, which they cultivate in the south of France and Italy for the purpose of feeding the silk-worm. But if it is stripped too often, in the season it requires its rest.

860. The decoction of a tree, or the stripping of it bark, may be either intentional or accidental, partial or total. If it is partial, and affects the epidermis only, then it is again regenerated, as in the case of slight incision, without leaving any scar. But if the epidermis of the petal, leaf, or fruit, is destroyed, it is not again regenerated, nor is the wound healed up, except by means of a scar. Such is the case also
and with all decortications that penetrate deeper than the epidermis, particularly if the wound is not protected from the direct action of the air: if the depths of these cracks reach to the wood, then new bark issues from between the bark and wood, and spreads till it covers the wound. But the result is not the same when the wound is covered from the air. In the season of the flowering of the sap Du Hamel detached a ring of bark, of three or four inches in breadth, from the trunk of a large young elm, taking care that the decortications did not cover the wound of the ring, by surrounding it with a tube of glass cemented above and below to the trunk. After a few days the tubes became cloudy within, particularly when it was hot; but when the air became cool, the cloud condensed and fell in drops to the bottom. At last there began to appear, as if exuding from between the upper part of the circumference, as if exuding from between the longitudinal fibres of the alburnum, a number of gelatinous drops. They were not connected with the scurfy substance at the top, but seemed to arise from small slips of the liber that had not been completely detached. Their first appearance was that of small, rubbery matter, sometimes brought off, more generally by checks produced by cold or injuries from excessive heat, or long continued drought. Fruit is often ripened prematurely by the puncture of insects; and a pine-apple of almost any age may be thrown into an hour by a two or three hour's exposure to frosty weather in winter, or by scourching the roots in an overhot tunnel at any season.

Sect. II. Diseases.

873. Diseases are corrupt affections of the vegetable body, arising from a vitiated state of its juices, and tending to injure the habitual health either of the whole or part of the plant. The diseases that occur the most frequently among vegetables are the following: Blight, smut, mildew, honey-dew, dropsy, flux of juices, gangrene, etiolation, suffocation, contortion, consumption.

874. Blight. Much has been written on the nature of blight; and in proportion as words have been multiplied on the subject, the difficulties attending its elucidation have increased.

875. The blight, or blast, was well known to the ancient Greeks, who were however totally ignorant of its cause, regarding it merely as a blast from heaven, indicating the wrath of their offended deities. It had utterly insensible to the Roman writers also to the Romans, and the enumeration of the rusts was no less well regarded in the same light as the Greeks, and even believed to be under the direction of a particular deity, Rubigus, whom they solemnly invoked that blight might be kept from corn and trees. It is still well known from its effects to every one having the least knowledge of the garden or garden labours; yet it has been very frequently met with of late in many countries, and there is no one cause that will account for all the different cases of blight, or disease going by the name of blight; though they have been supposed to have all the same origin. If we take the term in its most general acceptation I think it will include at least three distinct species—blight originating in cold and frosty winds, blight originating in seed, and blight originating in the immediate propagation of a sort of small and parasitical fungus.

876. Blight, originating in cold and frosty winds, is often occasioned by the cold and easterly winds of spring, which nip and destroy the tender shoots of the plant, by stopping the current of the juices. The leaves which are thus deprived of their due nourishment wither and fall, and the juices that are now stopped in their passage swell and burst the vessels, and become the food of innumerable little insects that soon after make their appearance. Hence they are often mistaken for the cause of the disease itself; the farmer supposing they are want of the key, wind, or east wind, and the cause of the disease to be the incompetence of the blight, or the want of the east wind, or east wind. The east wind is forming a protection for the eggs of insects, and their multiplication will no doubt contribute to the spreading of the disorder, as they always breed fast where they find plenty of food. But a similar disease is often occasioned by the early frost of spring. If the weather is prematurely mild, the blossom is prematurely produced, and with that, which is very necessary to be prevented, the east wind is occasioned by the judicious use of the east wind. For it is very often happened that this premature blossom is totally destroyed by subsequent frosts, as well as both the leaves and shoots, which consequently wither and fall, and injure if they do not actually kill the plant. This evil is also augmented by the unskilful gardener, even in attempting to prevent it; that is, by marring up his trees too closely, or by keeping them covered in the course of the day, and thus rendering the shoots so tender that they can scarcely fail to be destroyed by the next frost.

877. Blight, originating in sultry and pestilential vapor, generally happens in the summer when the grain has attained to its full growth, and when there are no cold winds or frosts to occasion it. Such was the blight that used to damage the vineyards of ancient Italy, and which is yet found to damage our hop-plantations and wheat-crops. The Romans had observed that it generally happened after short but heavy showers of rain, though not necessarily so, and have observed that the season of the ripening of the grain, and that of the middle of the vineyard suffered the most. This corresponds pretty nearly to what is in this country called the fire-blaze among hops, which has been observed to take place, most commonly about the end of July, when there has been rain with a hot gale preceding. The immediate objects of the disease are affected whether the blight is general or partial, and is almost always the point in which it originates. In a particular case that was minutely observed, the damage happened a little before noon, and the blight ran in a line forming a right angle with the sun's beams at that time of the day. There was but little wind, which was however in ripening, and at the beginning of the disease it was considered as preceding any thing expected from such a soil. A week afterwards a portion of the crop, on the east side of the field, to the extent of several acres, was totally destroyed; being shrunk and shrivelled up to less than half the size of what it had formerly been, and so withered and blasted as not to appear to belong to the same field. The rest of the poor produces a faint crop.

878. Blight, originating in fungi, attacks the leaves or stem both of herbaceous and woody plants, such as euphorbia cyparissias, berberis vulgaris, and rhamnus cathartica, but more generally and particularly our most useful grains, wheat, barley, and oats. By this name is generally assumed the appearance of a rusty-looking powder that soils the finger when touched. In March 1807, some blades of wheat were examined by Keight that were attacked with this species of blight; the appearance was that of a number of dusty-looking spots or patches dispersed over the surface of the leaf, exactly like that of the seeds of dorseferous ferns bursting their indium. Upon more minute inspection these patches were found to
DISEASES OF VEGETABLES.

consist of thousands of small globules collected into groups beneath the epidermis, which they raised up in a sort of blister and at last burst. Some of the globules seemed as if imbedded even in the longitudinal vessels of the blade. They were of a yellowish or rusty brown, and somewhat transparent. But these groups of globules have been ascertained by Sir J. Banks to be patches of minute fungus, the seeds of which, as they float in the air, enter the pores of the epidermis of the leaf, particularly if the plant is sickly; or they exist in the manure or soil, and enter by the pores of the root. (Sir J. Banks on Blight, 1806.) This fungus has been figured by Sowerby, and by F. Bauer, and crew. It is known among farmers by the name of red rust, and leaves it does not materially injure the crop. But there is another species of fungus known to the farmer by the name of red gum, which attacks the ear only, and is extremely prejudicial. In the aggregate it consists of groups of minute globules interspersed in the epidermis, and leaves it does not put any exudation, but it does not injure the plant. They are deposited on the surface of the plant by means of a black powder, but upon the soil, and they are deposited by the fungus, it may be for want of the peculiar food requisite for perfecting the grain; it being known that the fruit or seeds of many plants contain primitive principles not found in the rest of the plant. The grain of wheat contains gluten and phosphate of lime, and if there are wanting in the soil, that is, or the manured earths in which the plant grows, it will be unable to perfect its fruit, which of consequence becomes more liable to disease. (New Theory of Agr. &c.)

879. Smut is a disease incidental to cultivated corn, by which the farina of the grain, together with its proper integuments and even part of the husk, is converted into a black soot-like powder. If the injured ear is struck with the finger, the powder will be dispersed like a cloud of black smoke; and if a portion of the powder is wetted by a drop of water and put under the microscope, it will be found to consist of millions of minute and transparent globules, which seem to be composed of a clear and glary fluid encompassed by a thin and skinny membrane. This disease does not affect the whole body of the crop, but the smutted ears are sometimes very numerously dispersed throughout it. Some have attributed it to the soil in which the grain is sown, and others have attributed it to the seed itself, alleging that smutted seed will produce a smutted crop. But in all this there seems to be a great deal of doubt. Willdenow regards it as originating in a small fungus, which multiplies and extends till it occupies the whole ear. (Princip. of Bot. p. 356.) But F. Bauer of Kew, seems to have ascertained it to be merely a morbid swelling of the ear, and not at all connected with the growth of a fungus. (Smith's Introd. p. 348.) It is said to be prevented by steeping the grain before sowing in a weak solution of arsenic. But besides the disease called smut there is also a disease analogous to it, or a different stage of the same disease, known to the farmer by the name of bags or smut-balls, in which the nucleus of the seed only is converted into a black powder, whilst the ovary, as well as the husk, remains sound. The ear is not much altered in its external appearance, and the diseased grain contained in it will even bear the operation of threshing, and consequently mingle with the bulk. But it is always readily detected by the experienced buyer, and fatal to the character of the sample. It is said to be prevented as in the case of smut.

880. Mildew is a thin and whitish coating with which the leaves of vegetables are sometimes covered, occasioning their decay and death, and injuring the health of the plant. It is frequently found on the leaves of tussilago farfara, humulus lupulus, corylos avellana, and the white and yellow dead-nettle. It is found also on wheat in the shape of a glutinous exudation, particularly when the days are hot and the nights without dew. Willdenow says it is occasioned by the growth of a fungus of great minuteness, the mucor crisyphe of Linnaeus; or by a sort of whitish slime which some species of aphides deposit upon the leaves. J. Robertson (Hort. Trans. v. 178.) considers it as a minute fungus of which different species attack different plants. Sulphur he has found the only specific cure. In cultivated crops mildew is said to be prevented by manuring with soot.

881. Honey-dew is a sweet and clammy substance which congeulates on the surface of the leaves during hot weather, particularly on the leaves of the oak-tree and beech, and is regarded by Curtis as being merely the dung of some species of aphides. This seems to be the opinion of Willdenow also, and it is in doubt possible that it may be the case in some instances or species of the disease. But Sir J. E. Smith contends that it is not always so, or that there are more species of honey-dew than one, regarding it particularly as being an exudation, at least in the case of the beech, whose leaves are, in consequence of an unfavorable wind, apt to become covered with a sweet sort of glutinous coating, similar in flavor to the fluid obtained from the trunk.

882. It is certain, however, that saccharine exudations are found on the leaves of many plants, though not always distinguished by the name of honey-dew; which should not perhaps be applied except when the exudation occasions disease. But if it is to be applied to all saccharine exudations whatever, then we must include under the appellation of honey-dew, the saccharine exudations observed on the orange-tree by De la Hire, together with that of the lime-tree which is more glutinous, and of the poplar which is more resinous; as also that of the eustus creticus, and of the manna which exudes from the ash-tree of Italy and larch of France. It is also possible that the exudation of excrement constituting honey-dew may occasionally occur without producing disease; for if it should happen to be washed off soon after by rains or heavy dews, then the leaves will not suffer. Washing is therefore the palliative: judicious culture the preventive.

883. Plants are also liable to a disease which affects them in a manner similar to that of the dropsy in animals, arising from long continued rain or too abundant watering.
Willdenow describes it as occasioning a preternatural swelling of particular parts, and inducing putrefaction. It is said to take place chiefly in bulbous and tuberous roots, which are often found much swelled after rain. It affects fruits also, which it renders watery and insipid. It prevents the ripening of seeds, and occasions an immoderate production of roots from the stem.

884. Succulent plants. This disease generally appears in consequence of excessive waterings, and is generally incurable. The leaves drop, even though plump and green; and the fruit rots before reaching maturity. In this case the absorption seems to be too great in proportion to the transpiration; but the soil when too much manured has this similar effects. Du Hamel planted some elms in a soil that was particularly well manured, and accordingly they puzzled with great vigor for some time; but at the end of five or six years they all died suddenly. The bark was found to be detached from the wood, and the cavity filled up with a reddish-colored water. The symptoms of this disease suggest the palliatives; and the preventive is ever the same — judicious culture.

885. Flux of juices. Some trees, but particularly the oak and birch, are liable to a great loss of sap either bursting out spontaneously, owing to a superabundance of sap, or issuing from accidental wounds; sometimes it is injurious to the health of the plant, and sometimes not.

886. There is a spontaneous extravasation of the sap of the vine, known by the name of the tears of the vine, which is not always injurious. As it often happens that the root imbipes sap, which the leaves are not yet prepared to throw off, because not yet sufficiently expanded, owing to an inlent season, the sap which is first carried up, being propelled by that which follows, ultimately forces its way through all obstructions, and exudes from the bud. But this is observed only in cold climates; for in hot climates where the development of the leaves is not obstructed by cold, they are ready to elaborate the sap as soon as it reaches them. There is also a spontaneous extravasation in some cases of root-cysts, and the gum which exudes from cherry, plum, peach, and almond trees, is seldom detrimental to their health, except when it insinuates itself into the other vessels of the plant and occasions obstructions.

887. By a extravasation of gum is intended a disease, and one for which there is seldom any remedy. It is generally the consequence of an unsuitably soil, situation, or climate. Cold raw summers will produce it in the peach, apricot, and more under sorts of plum and cherry; or grafting these fruits on diseased stocks. Cutting out the part and applying a covering of loam or tar and charcoal appears to exclude the air and prevent it; but the only effectual method, where it can be practised, is to take up the tree and place it in a suitable soil and situation.

888. The extravasation and corruption of the ascending or descending juices, has been known to occasion a fissure of the solid parts. Sometimes the fissure is occasioned by means of frost, forming what is called a double albumen; that is, first a layer that has been injured by the frost, and then a layer that passes into wood. Sometimes a layer is partially affected, and that is generally owing to a sudden and partial thaw on the south side of the trunk, which may be followed again by a sudden frost. In this case the albumen is split, by means of the expansion of the wood.

889. Chiblains. But clefts thus occasioned often degenerate into chiblains that discharge a blackish and acrid fluid to the great detriment of the plant, particularly if the sores are so situated that rain or snow will readily lodge in them, and become putrid. The same injury may be occasioned by the bite or puncture of insects while the shoot is yet tender; and as no vegetable ulcer heals up of its own accord, the sooner a cure is attempted the better, as it will, if left to itself, ultimately corrode and destroy the whole plant, bark, wood, and pith. The only palliative is the excision of the part affected, and the application of a coat of grafting wax. (Willdenon, p. 334.)

890. Gangrene. Of this disorder there are two varieties, the dry and the wet. The former is occasioned by means of excessive heat or excessive cold. If by means of cold, it attacks the leaves of young shoots and causes them to shrink up, converting them from green to black; as also the inner bark, which it blackens in the same manner, so that it is impossible to save the plant except by cutting it to the ground. If by means of heat, the effects are nearly similar, as may oftentimes be seen in gardens, or even in forests, where the foresters are allowed to clear away the moss and withered leaves from the roots. Sometimes the disease is occasioned by the too rapid growth of a particular branch, depriving the one that is next it of its due nourishment, and hence inducing its decay. Sometimes it is occasioned by means of parasitical plants, as in the case of the bulbs of the saffron, which a species of lycoperdon often attaches itself to and totally corrupts.

891. Dry gangrene. The harnattan winds of the coast of Africa kill many plants, by means of inducing a sort of gangrene that withers and blackens the leaves, and finally destroys the whole plant. The nopal of Mexico is also subject to a sort of gangrene that begins with a black spot, and extends till the whole leaf or branch rots off, on which occasions the leaves are affected. But gangrene may affect bushes, trees, and shrubs. It affects also the flowers and fruit. Sometimes it attacks the roots also, but rarely the stem. It seems to be owing, in many cases, to too wet or too rich a soil; but it may originate in contagion, and may be caught by infection. But the nopal is subject also to a disease called by Thiery la dissolution, considered by Sir J. E. Smith as distinct from gangrene, and which appears to be Willdenon's dry gangrene. A joint of the nopal, or a whole branch, and sometimes an entire plant, changes in the space of a single hour, from a state of apparent health to a state of putrefaction or dissolution. Now its surface is verdant and shining, and in a few minutes changes to a watery jelly. Its brittleness is greater. If the substance is cut into, the parts are found to have lost all cohesion, and are quite rotten; the attempt at a cure is by speedy amputation below the diseased part. Sometimes the vital principle collecting and exerting all its energies, makes a stand as it were against the encroaching disease, and throws off the infected part. (Smith's Introduction, p. 340.)

892. Etiolation. Plants are sometimes affected by a disease which entirely destroys their verdure, and renders them pale and sickly. This is called etiolation, and may arise merely from want of the agency of light, by which the extraction of oxygen is effected, and the leaf rendered green. And hence it is that plants placed in dark rooms, or between great masses of stone, or in the clefts of rocks, or under the shade of other trees, look always peculiarly pale. But if they are removed from such situations, and exposed
to the action of light, they will again recover their green color. Etiolation may also ensue from the deprecation of insects nestling in the radicle, and consuming the food of the plant, and thus debilitating the vessels of the leaf so as to render them insusceptible of the action of light. This is said to be often the case with the radicles of secale cereale; and the same result may also arise from poverty of soil.

893. Suffocation. Sometimes it happens that the pores of the epidermis are closed up, and transpiration consequently obstructed, by means of some extraneous substance that attaches itself to and covers the bark. This obstruction induces disease, and the disease is called suffocation.

894. Sometimes it is occasioned by the immediate growth of lichens upon the bark covering the whole of the plant, as may be often seen in fruit-trees, which it is necessary to keep clean by means of scraping off the lichens, at least from the smaller branches. For if the young branches are thus covered with lichens, so that the bark cannot perform its proper functions, the tree will soon begin to languish, and will finally become covered with fungi, inducing or resulting from decay, till it is at last wholly choked up.

895. But a similar effect is also occasionally produced by insects, in feeding upon the sap or shoot. This may also be accomplished in the case of apple, when some small insects are thus covered upon the tender shoot in such multitudes as to cover it from the action of the external air altogether. It may be exemplified also in the case of Coccus wespertinus and Acrasius tellarius, insects that infest hot-house plants, the latter by spinning a fine and delicate web over the leaf, and thus preventing the action of atmospheric air. Insects are to be removed either by the hand or other mechanical means, or destroyed by excess of some of the elements of their nutrition, as heat, or cold, or moisture, where such excess does not prove injurious to the plant; or by a composition either fluid or otherwise, which shall have the same effects. Prevention is better than cure. Particular attention should be paid to the propagation of the insects or vermin, by destroying their embryo progeny, whether oviparous or otherwise.

896. Sometimes the disease is occasioned by an extravasation of juices which coagulate on the surface of the leaf, and as to form a sort of crust, but as they are not soon burnt off, they cause the further expansion of the leaf. Hence the top shoots decrease in size every succeeding year, because sufficient supply of sap cannot be obtained through the prop根ive. This is about the same as that which also occurs when the action of the heart is too feeble to propel the blood through the whole of the system: for then the extremities are always the first to suffer. And perhaps it may account also for the fact, that in bad soils and unfavorable seasons, when the ear of barley is not wholly perfected, yet a few of the lower grains are always completely developed. (Smith's Introduction, p. 344.)

898. Contortion. The leaves of plants are often injured by the means of puncture of insects, so as to induce a sort of disease that discovers itself in the contortion or convolution of the margin, or wrinkled appearance of the surface. The leaves of the apricot, peach, and nectarine, are extremely liable to be thus affected in the months of June and July.

899. The leaf that has been punctured soon begins to assume a rough and wrinkled figure, and a reddish and scrofulous appearance, particularly on the upper surface. The margins roll inwards on the under side, and enclose the eggs which are scattered irregularly on the surface, giving it a blackish and granular appearance, but without materially injuring its health. In the vine, the substance deposited on the leaf is whitish, giving the under surface a sort of a frosted appearance, but not occasioning the red and scrofulous aspect of the upper surface of the leaf of the nectarine. In the poplar, the eggs when first deposited resemble a number of small and hoary vesicles containing a sort of clear and colorless fluid. The leaf then becomes refaced and constricted, enclosing the eggs, with a few reddish protuberances on the upper surface. The embryo is nourished by this fluid, and the hoary appearance is converted into a fine cottony down, white and glistening. The time in which the leaf is thus protected from insects when fully expanded; and hence the gnawed appearance it so often exhibits. The injury seems to be occasioned by some species of puceran depositing its eggs in the parenchyma, generally about the angulate margin of the leaf where they are thus concealed, at first green, and afterwards brown or scarlet, sometimes in patches, and sometimes pervading the whole leaf; as in the case of the vine. Under this injury the leaf is hatched; and then the young insect gnaws and injures the leaf, leaving a hole, or scar of a burnt or singed appearance. Sometimes the upper surface of the leaf is covered with clusters of very small punctures made by the insects. They seem to be occasioned by means of a puncture made on the under surface, on which a number of openings are discoverable, penetrating into the warts, which are hollow and villous within. The disease admits of palliation by watering frequently over the leaves; and by removing such as are the most contorted and covered with barren bars.

900. Consumption. From barren or improper soil, unfavorable climate, careless planting, or too frequent flowering exhausting the strength of the plant, it often happens that disease is induced which terminates in a gradual decline and wasting away of the plant, till at length it is wholly dried up. Sometimes it is also occasioned by excessive drought, or by dust lodging on the leaves, or by flames issuing from manufactories which may happen to be situated in the neighbourhood, or by the attacks of insects.

901. There is a consumptive affection that frequently attacks the pine-tree, called Terebæ Pinarum (Wilkesham, Prin. Bot., p. 321.), which attacks the albumen and inner bark chiefly, and seems to proceed from long continued drought, or from frost suddenly succeeding mild or warm weather, or heavy winds. The leaves assume a tinge of yellow, bordering upon red. A great number of small drops of resin exude from the middle of the boughs, of a putrid odour. The bark exfoliates, and the albumen becomes blackened, and the tree exudes a fluid secreted by itself from top to bottom. The tree is thus supplied with insects, and the disease is incurable, inducing inevitably the total decay and death of the individual. The preventive is obviously good culture, so as to maintain vigorous health: palliatives may be employed according to the apparent cause of the disease.

Sect. III. Natural Decay.

902. Although a plant should not suffer from the influence of accidental injury, or from disease, still there will come a time when its several organs will begin to experience the approaches of a natural decline insensibly stealing upon it, and at last destroying death. The duration of vegetable existence is very different in different species. Yet in the vegetable, as well as in the animal kingdom, there is a term or limit set, beyond which the
individual cannot pass. Some plants are annuals and last for one season only, springing up suddenly from seed, attaining rapidly to maturity, producing and again sowing their seeds, and afterwards immediately perishing. Such is the character of the various species of corn, as exemplified in oats, wheat, and barley. Some plants continue to live for a period of two years, and are therefore called biennials, springing up the first year from seed, and producing roots and leaves, but no fruit; and in the second year producing both flower and fruit, as exemplified in the carrot, parsnep, and caraway. Other plants are perennials, that is, lasting for many years; of which some are called under-shrubs, and die down to the root every year; others are called shrubs, and are permanent both by the root and stem, but do not attain to a great height or great age; others are called trees, and are not only permanent by both root and stem, but attain to a great size, and live to a great age. But even of plants that are woody and perennial, there are parts which perish annually, or which are at least annually separated from the individual; namely, the leaves, flowers, and fruit, leaving nothing behind but the bare caudex, which submits in its turn to the ravages of time, and ultimately to death.

905. The decay of the temporary organs, which takes place annually, is a phenomenon familiar to every body, and comprehends the fall of the leaf, the fall of the flower, and the fall of the fruit.

904. The fall of the leaf, or annual defoliation of the plant, commences for the most part with the colds of autumn, and is accelerated by the frosts of winter, that strip the forest of its foliage, and the landscape of its verdure. But there are some trees that retain their leaves throughout the whole of the winter, though changed to a dull and dusky brown, and may be called ever-clothed trees, as the beech; and some are others that retain their verdure throughout the year, and are denominated evergreens, as the holly. The leaves of both sorts ultimately fall in the spring. Sir J. E. Smith considers that leaves are thrown off by a process similar to that of the sloughing of diseased parts in the animal economy; and Keith observes, that if it is necessary to illustrate the fall of the leaf by any analogous process in the animal economy, it may be compared to the shedding of the antlers of the stag, or of the hair or feathers of other beasts or birds, which being, like the leaves of plants, distinct and peculiar organs, fall off, and are regenerated annually, but do not slough.

905. The flowers, which, like the leaves, are only temporary organs, are for the most part very short-lived; for as the object of their production is merely that of effecting the impregnation of the germs, that object is no sooner obtained than they begin again to give indications of decay, and speedily fall from the plant; so that the most beautiful part of the vegetable is also the most transient.

906. The fruit, which begins to appear conspicuous when the flower falls, expands and increases in volume, and, assuming a peculiar hue as it ripens, ultimately detaches itself from the parent plant, and drops into the soil. But it does not in all cases detach itself in the same manner: thus, in the bean and pea the seed-vessels opens and lets the seeds fall out, while in the apple, pear, and cherry, the fruit falls entire, enclosing the seed, which escapes when the pericarp decays. Most fruits fall soon after ripening, as the cherry and apricot, if not gathered; but some remain long attached to the parent plant after being fully ripe, as in the case of the fruit of euonymus, and mespilus. But these, though tenacious of their hold, detach themselves at last, as well as all others, and bury themselves in the soil, about to give birth to a new individual in the germination of the seed. The fall of the flower and fruit is accounted for in the same manner as that of the leaf.

907. Decay of the permanent organs. Such then is the process and presumptive rationale of the decay and detachment of the temporary organs of the plant. But there is also a period beyond which even the permanent organs themselves can no longer carry on the process of vegetation. Plants are affected by the infirmities of old age as well as animals, and are found to exhibit also similar symptoms of approaching dissolution. The root refuses to imbibe the nourishment afforded by the soil, or if it does imbibe a portion, it is but feebly propelled, and partially distributed, through the tubes of the albumen; the elaboration of the sap is now effected with difficulty as well as the assimilation of the proper juice, the descent of which is almost totally obstructed; the bark becomes thick and woody, and covered with moss or lichens; the shoot becomes stunted and diminutive; and the fruits palpably degenerate, both in quantity and quality. The smaller or terminal branches fade and decay the first, and then the larger branches also, together with the trunk and root; the vital principle gradually declines without any chance of recovery, and is at last totally extinguished. When life is extinguished, nature hastens the decomposition; the surface of the tree is overrun with lichens and mosses, which attract and retain the moisture; the empty pores imbibe it, and putrefaction speedily follows. Then come the tribes of fungi, which flourish on decaying wood, and accelerate its corruption; beetles and caterpillars take up their abode under the bark, and bore innumerable holes in the timber; and woodpeckers in search of insects pierce it more deeply, and excavate large hollows, in which they place their nests. Frost, rain, and heat assist, and the whole mass crumbles away, and dissolves into a rich mould. (Dia log. on Bot. p. 365.)

CHAP. X.

Vegetable Geography and History, or the Distribution of Vegetables relatively to the Earth and to Man.

908. The science of the distribution of plants, Humboldt observes (Essai sur la Geographie des Plantes, &c. 1807), considers vegetables in relation to their local associations in
Book I. DISTRIBUTION OF VEGETABLES. 197
different climates. It points out the grand features of the immense extent which plants occupy, from the regions of perpetual snow to the bottom of the ocean, and to the interior of the globe, where, in obscure grottoes, cryptogamous plants vegetate, as unknown as the insects which they nourish. The superior limits of vegetation are known, but not the inferior; for every where in the bowels of the earth are germs which develop themselves when they find a space and nourishment suitable for vegetation. On taking a general view of the disposition of vegetables on the surface of the globe, independently of the influence of man, that disposition appears to be determined by two sorts of causes, geographical and physical. The influence of man, or of cultivation, has introduced a third cause, which may be called civil. The different aspects of plants, in different regions, has given rise to what may be called their characteristic, or picturesque distribution; and the subject of distribution may be also considered relatively to the systematic divisions of vegetables, their arithmetical proportions, and economical applications.

SECT. I. Geographical Distribution of Vegetables.

909. The territorial limits to vegetation are determined in general by three different causes: —1. By sandy deserts, which seeds cannot pass over either by means of winds or birds, as that of Sahara, in Africa; 2. By seas too vast for the seeds of plants to be drifted from one shore to the other, as in the ocean; while the Mediterranean sea, on the contrary, exhibits the same vegetation on both shores; and, 3. By long and lofty chains of mountains. To these causes are to be attributed the fact, that similar climates and soils do not always produce similar plants. Thus in certain parts of North America, which altogether resemble Europe in respect to soil, climate, and elevation, not a single European plant is to be found. The same remark will apply to New Holland, the Cape of Good Hope, Senegal, and other countries, as compared with countries in similar physical circumstances, but geographically different. The separation of Africa and South America, Humboldt considers, must have taken place before the development of organised beings, since scarcely a single plant of the one country is to be found in a wild state in the other.

SECT. II. Physical Distribution of Vegetables.

910. The natural circumstances affecting the distribution of plants, may be considered in respect to temperature, elevation, moisture, soil, and light.

911. Temperature has the most obvious influence on vegetation. Every one knows that the plants of hot countries cannot in general live in such as are cold, and the contrary. The wheat and barley of Europe will not grow within the tropics; the same remark applies to plants of still higher latitudes, such as those within the polar circles, which cannot be made to vegetate in more southern latitudes; nor can the plants of more southern latitudes be made to vegetate there. In this respect, not only the medium temperature of a country ought to be studied, but the temperature of different seasons, and especially of winter. Countries where it never freezes; those where it never freezes so strong as to stagnate the sap in the stems of plants; and those where it freezes sufficiently strong to penetrate into the cellular tissue; form three classes of regions in which vegetation ought to differ. But this difference is somewhat modified by the effect of vegetable structure, which resists, in different degrees, the action of frost; thus, in general, trees which lose their leaves during winter resist the cold better than such as retain them; resinous trees more easily than such as are not so; herbs of which the shoots are annual and the root perennial, better than those where the stems and leaves are persisting; annuals which flower early, and whose seeds drop and germinate before winter, resist cold less easily than such as flower late, and whose seeds lie dormant in the soil till spring. Monocotyledonous trees, which have generally persisting leaves and a trunk without bark, as in palms, are less adapted to resist cold than dicotyledonous trees, which are more favourably organised for this purpose, not only by the nature of their proper juice, but by the disposition of the cortical and albuminous layers, and the habitual carbonisation of the outer bark. Plants of a dry nature resist cold better than such as are watery; all plants resist cold better in dry winters than in moist winters; and an attack of frost always does most injury in a moist country, in a humid season, or when the plant is too copiously supplied with water.

912. Some plants of firm texture, but natives of warm climates, will endure a frost of a few hours' continuance, as the orange at Genoa (Humboldt, De Distributione Plantarum); and the same thing is said of the palm and pine-apple, facts most important for the gardener. Plants of delicate texture, and natives of warm climates, are destroyed by the slightest attack of frost, as the phaseolus, nasturtium, &c.

913. The temperature of spring has a material influence on the life of vegetables; the injurious effects of late frosts are known to every cultivator. In general, vegetation is favored in cold countries by exposing plants to the direct influence of the sun; but this excitement is injurious in a country subject to frosts late in the season: in such cases, it is better to retard than to accelerate vegetation.
914. The temperature of summer, as it varies only by the intensity of heat, is not productive of so many injurious accidents as that of spring. Very hot dry summers, however, destroy many delicate plants, and especially those of cold climates. A very early summer is injurious to the germination and progress of seeds; a short summer to their ripening, and the contrary.

915. Autumn is an important season for vegetation, as it respects the ripening of seeds; hence where that season is cold and humid, annual plants, which naturally flower late, are never abundant, as in the polar regions; the effect is less injurious to perennial plants, which generally flower earlier. Frosts early in autumn are as injurious as those which happen late in spring. The conclusion, from these considerations, obviously is, that temperate climates are more favorable to vegetation than such as are either extremely cold or extremely hot. But the warmer climates, as Keith observes, are more favorable upon the whole to vegetation than the colder, and that nearly in proportion to their distance from the equator. The same plants, however, will grow in the same degree of latitude, throughout all degrees of longitude, and also in correspondent latitudes on different sides of the equator; the same species of plants, as some of the palms and others, being found in Japan, India, Arabia, the West Indies, and part of South America, which are all in nearly the same latitudes; and the same species being also found in Kamschatka, Germany, Great Britain, and the coast of Labrador, which are all also in nearly the same latitudes. (Willdenow, p. 374.)

916. The most remarkable circumstances respecting the temperature in the three zones, is exhibited in the following Table by Humboldt. The temperature is taken according to the centigrade thermometer. The fathom is 6 French feet, or 6.39453 English feet.

917. Elevation, or the height of the soil above the level of the sea, determines, in a very marked manner, the habitation of plants. The temperature lessens in regular gradation, in the same manner as it does in receding from the equator, and six hundred feet of elevation, De Candolle states, are deemed equal to one degree of latitude, and occasion a diminution of temperature equal to 23° of Fahrenheit; 300 feet being nearly equal to half a degree. Mountains 1000 fathoms in height, at 46° of latitude, have the mean temperature of Lapland; mountains of the same height between the tropics enjoy the temperature of Sicily; and the summits of the lofty mountains of the Andes, even where situated almost directly under the equator, are covered with snow as eternal as that of the north pole.
918. Hence it is that plants of high latitudes live on the mountains of such as are much lower, and thus the plants of Greenland and Lapland are found on the Alps and Pyrenees. At the foot of Mount Ararat (fig. 67.), Tournefort met with plants peculiar to Armenia; above these he met with plants which are found also in France; at a still greater height he found himself surrounded with such as grow in Sweden; and at the summit with such as vegetate in the polar regions. This accounts for the great variety of plants which are often found in a Flora of no great extent; and it may be laid down as a botanical axiom, that the more diversified the surface of the country, the richer will its Flora be, at least in the same latitudes. It accounts also, in some cases, for the want of correspondence between plants of different countries though placed in the same latitudes; because the mountains or ridges of mountains, which may be found in the one and not in the other, will produce the greatest possible difference in the character of their Floras. And to this cause may generally be ascribed the diversity that often actually exists between plants growing in the same latitudes, as between those of the north-west and north-east coasts of North America, as also of the south-west and south-east coasts; the former being more mountainous, the latter more flat. Sometimes the same sort of difference takes place between the plants of an island and those of the neighbouring continent; that is, if the one is mountainous and the other flat; but if they are alike in their geographical delineation, then they are generally alike in their vegetable productions.

919. Cold and lofty situations are the favorite habitations of most cryptogamic plants of the terrestrial class, especially the fungi, algae, and mosses; as also of plants of the class Tetradynamia, and of the Umbellatae and Syngenetian tribes; whereas trees and shrubs, ferns, parasitic plants, lilies, and aromatic plants, are most abundant in warm climates; only this is not to be understood merely of geographical climates, because, as we have seen, the physical climate depends upon altitude. In consequence of which, combined with the ridges and directions of the mountains, America and Asia are much colder in the same degrees of northern latitude than Europe. American plants, vegetating at forty-two degrees of northern latitude, will vegetate very well at fifty-two degrees in Europe; the same, or nearly so, may be said of Asia; which, in the former case, is perhaps owing to the immense tracts of woods and marshes covering the surface, and in the latter, to the more elevated and mountainous situation of the country affecting the degree of temperature. So also Africa is much hotter under the tropics than America; because in the latter the temperature is lowered by immense chains of mountains traversing the equatorial regions, while in the former it is increased by means of the hot and burning sands that cover the greater part of its surface.

920. Elevation influences the habits of plants in various ways; — by exposing them to the wind; to be watered by a very fresh and pure water from the melting of adjoining snow; and to be covered in winter by a thick layer of snow, which protects them from severe frosts. Hence many alpine plants become frozen during winter in the plains, and in gardens which are naturally warmer than their natural stations. In great elevations, the diminution of the density of the air may also have some influence on vegetation. The rarity of the atmosphere admits a more free passage for the rays of light, which, being in consequence more active, ought to produce a more active vegetation. Experience seems to prove this in high mountains; and the same effect is produced in high latitudes by the length of the day. On the other hand, vegetables require to absorb a certain quantity of oxygen gas from the air during the night; and as they find less of that in the rarefied air of the mountains, they ought to be proportionally feeble and languishing. According to experiments made by Theodore de Saussure, plants which grow best in the high Alps are those which require to absorb least oxygen during the night; and, in this point of view, the shortness of the nights near the poles correspond. These causes, however, are obviously very weak, compared to the powerful action of temperature.
921. *Great anomalies* are found in the comparative height in which the same plant will grow in different circumstances. In countries situated under the equator, the two sides of the mountain are of the same temperature, which is solely determined by elevation; but in countries distant from it, the warmest side is that towards the south, and the zones of plants, instead of forming lines parallel to the horizon, incline towards the north. The reason, in both cases, is sufficiently obvious. In the temperate zone we find the same plants frequently on low and elevated situations, but this is never the case between the tropics.

922. **Altitude influences the habits of aquatic**; thus some aquatics float always on the surface of the water, as lemmna, while others are either partially or wholly immersed. Such aquatics as grow in the depths of the sea are not influenced by climate; but such as are near the surface are influenced by climate, and have their habitations affected by it.

923. **The moisture, or mode of watering natural to vegetables**, is a circumstance which has a powerful influence on the facility with which plants grow in any given soil. The quantity of water absolutely necessary for the nourishment of plants, varies according to their tissue; some are immersed, others float on its surface; some grow on the margin of waters, with their roots always moistened or soaked in it, others again live in soil slightly humid or almost dry. Vegetables which resist extreme drought most easily are, 1. Trees and herbs with deep roots, because they penetrate to, and derive sufficient moisture from, some distance below the surface; 2. Plants which, being furnished with very few pores on the epidermis, evaporate but little moisture from their surface, as the succulent tribe.

924. **The qualities of water**, or the nature of the substances dissolved in it, must necessarily influence powerfully the possibility of certain plants growing in certain places. But the difference in this respect is much less than would be imagined, because the food of one species of plant differs very little from that of another. The most remarkable case is that of salt-marshes, in which a great many vegetables will not live, whilst a number of others thrive there better than any where else. Plants which grow in marine marshes and those which grow in similar grounds situated in the interior of a country are the same. Other substances naturally dissolved in water appear to have much less influence on vegetation, though the causes of the habitations of some plants, such as those which grow best on walls, as peltaria, and in lime-rubbish, as thalipes, and other cruciferæ, may doubtless be traced to some salt (nitrate of lime, &c.) or other substance peculiar to such situations.

925. **The nature of the earth’s surface** affects the habitations of vegetables in different points of view: 1. As consisting of primitive earths, or the débris of rocks or mineral bodies; and, 2. As consisting of a mixture of mineral, animal, and vegetable matter.

926. **Primitive surfaces** affect vegetables mechanically according to their different degrees of moveableness or tenacity. In coarse sandy surfaces plants spring up easily, but many of them, which have large leaves or tall stems, are as easily blown about and destroyed. In fine, dry, sandy surfaces, plants with very delicate roots, as protea and erica, prosper; a similar earth, but moist in the growing season, is suited to bulbs. On clayey surfaces plants are more difficult to establish, but when established are more permanent: they are generally coarse, vigorous, and perennial in their duration.

927. With respect to the relative proportions of the primitive earths in these surfaces, it does not appear that their influence on the distribution of plants, is so great as might at first sight be imagined. Doubtless different earths are endowed with different degrees of absorbing, retaining, and parting with moisture and heat; and these circumstances have a material effect in a state of culture, where they are comminuted and exposed to the air; but not much in a wild or natural state, where they remain hard, firm, and covered with vegetation. The difference, with a few exceptions, is never so great but that the seeds of a plant which has been found to prosper well in one description of earth, will germinate and thrive as well in another composed of totally different earths, provided they are in a nearly similar state of mechanical division and moisture. Thus De Candolle observes, though the box is very common on calcareous surfaces, it is found in as great quantities in such as are schistous or granitic. The chestnut grows equally well in calcareous and clayey earths, in volcanic ashes, and in sand. The plants of Aira, a mountain entirely calcareous, grow equally well on the Vosges or the granitic Alps. But though the kind or mixture of earths seems of no great consequence, yet the presence of metallic oxides and salts, as sulphates of iron or copper, or sulphur alone, or alum, or other similar substances in a state to be soluble in water, are found to be injurious to all vegetation, of which some parts of Derbyshire and the marennes of Tuscany (Chateauneuf, let. 8.) are striking proofs. But excepting in these rare cases, plants grow nearly indifferently on all primitive surfaces, in the sense in which we here take these terms; the result of which is, that earths strictly or chemically so termed, have much less influence on the distribution of plants, than temperature, elevation, and moisture. Another
result is, as De Candolle has well remarked, that it is often a very bad method of culture to imitate too exactly the nature of the earth in which a plant grows in its wild state.

928. Mixed or secondary soils include not only primitive earths, or the débris of rocks, but vegetable matters — not only the medium through which perfect plants obtain their food, but that food itself. In this view of the subject the term soil is used in a very extensive acceptation, as signifying, not only the various sorts of earths which constitute the surface of the globe, but every substance whatever on which plants are found to vegetate, or from which they derive their nourishment. The obvious division of soils in this acceptation of the term is that of aquatic, terrestrial, and vegetable soils; corresponding to the division of aquatic, terrestrial, and parasitical plants.

929. Aquatic soils are such as are either wholly or partially inundated with water, and are fitted to produce such plants only as are denominated aquaticos. Of aquatics there are several subdivisions according to the particular situations they affect, or the degree of immersion they require.

One of the principal subdivisions of aquatics is that of marine plants, such as the fuci and many of the algae, which are very plentiful in the seas that wash the coasts of Great Britain, and are generally attached to stones and rocks in the shore. Some of them are always immersed; and others, which are situated above low water mark, are immersed and exposed to the action of the atmosphere alternately. But none of them can be made to vegetate except in the waters of the sea. Another subdivision of aquatics is that of alpine plants, such as thalas, and samolus, which occupy the bed of fresh water rivers, and vegetate in the midst of the running stream; being for the most part wholly immersed, as well as found only in such situations.

A third subdivision of aquatics is that of paludal or fen plants, being such as are peculiar to lakes, marshes, and stagnant or nearly still waters, but of which the bottom is often tolerably clear. In such situations you find the isoetes lacustris, flowering rush, water ranunculus, water violet, and a variety of others which uniformly affect such situations; some of them being wholly immersed, and others immersed only in part.

930. Earthy soils are such as emerge above the water and constitute the surface of the habitable globe, that is everywhere covered with vegetable productions. Plants affecting such soils, which comprise by far the greater part of the vegetable kingdom, are denominated terrestrial, being such as vegetate upon the surface of the earth, without having any portion immersed in water, or requiring any further moisture for their support beyond that which they derive from the earth and atmosphere. This division is, like the aquatics, distributed into several subdivisions according to the peculiar situations which different tribes affect.

931. Some of them are maritime, that is, growing only on the sea-coast, or at no great distance from it, such as statice, gaux, samolus, samphire, sea-pea.

932. Some are fluviales, that is, affecting the banks of rivers, such as lythrum, lycopus, eupatorium.

933. Some are lacustres, that is, affecting chiefly the plains, meadows, and cultivated fields, such as cardamine, tragopogon, agrostemma.

934. Some are damose, that is, growing in hedges and thickets, such as the bramble.

935. Some are ruderal, that is, growing on rubbish, such as Chenopodium album.

936. Some are status, that is, growing in woods or forests, such as stachys sylvatica, angelica sylvestris.

937. And, finally, some are alpine, that is, growing on the summits of mountains, such as poa alpina, epilobium alpinum, and many of the moses and lichens.

938. Vegetable soils are such as are formed of vegetating or decayed plants themselves, to some of which the seeds of certain other plants are found to adhere, as being the only soil fitted to their germination and development. The plants springing from them are denominated Parasitical, as being plants that will vegetate neither in the water nor earth, but on certain other plants, to which they attach themselves by means of roots that penetrate the bark, and from the juices of which they do often, though not always, derive their support. This last circumstance constitutes the ground of a subdivision of parasitical plants, into such as adhere to the dead or inert parts of other plants, and such as adhere to living plants, and feed on their juices.

939. In the first subdivision we may place parasitical mosses, lichens, and fungi, which are found as often, and in as great perfection on the stumps of rotten trees, and on rotten pales and stakes, as on trees that are yet vegetating; whence it is also plain that they do not derive their nourishment from the juices of the plants on which they grow, but from their decayed parts, and the atmosphere by which they are surrounded; the plant to which they cling serving as a basis of support.

940. In the second subdivision we may place all plants strictly parasitical, that is, all such as do actually abstract from the juices of the plant to which they cling the nourishment necessary to the development of their parts; and of which the most common, at least as being indigenous to Britain, are the Mistletoe, Dog's mercury, Broom-rape, and a sort of tuber that grows on the root of Saffron, and destroys it if allowed to spread.

941. The Mistletoe (Viscum album) is found for the most part on the apple-tree; but sometimes also on the oak. If its berry is made to adhere to the trunk or branch of either of the foregoing trees, which from its glutinous nature it may readily be made to do, it germinates by sending out a small globular body attached to a pedicle, which after it acquires a certain length bends towards the bark, whether above it or below it, into which it insinuates itself by means of a number of small fibres which it now protrudes, and by which it affects from the plant the nourishment necessary to its future development. When the root has thus fixed itself in the bark of the supporting tree, the stem of the parasite begins to ascend, at first smooth and tapering, and of a pale green colour, but finally protruding a multiplicity of branches and leaves. It seems to have been thought by some botanists that the roots of the Mistletoe penetrate even into the wood, as well as through the bark. But the observations of Du Hamel show that this opinion is not well founded. The roots are indeed often found within the wood, which they thus seem to have
penetrated by their own vegetating power. But the fact is, that they are merely covered by the additional layers of wood that have been formed since the fibres first inwitted themselves into the bark.  

945. The Oenotria europaeus, or Dodder (fig. 68), though it is to be accounted a truly parasitical plant in the issue, is yet not originally so. For the seed of this plant when it has fallen to the ground takes root originally by sending down its radicle into the soil and elevating its stem into the air. It is not yet, therefore, a parasitical plant. But the stem which is elevated above the surface lays hold of the first plant it meets with, though it is particularly partial to hops and nettles, and twines itself around it, attaching itself by means of little parasitical roots at the points of contact, and finally detaching itself from the soil altogether by the decay of the original root, and becoming a truly parasitical plant. Withering describes the plant in his arrangement as being originally parasitical, but this is certainly not the fact.

946. *Light* is a body which has very considerable influence on the structure of vegetables, and some also on their habitation. The fungi do not require the usual interludes of day, in order to decompose carbonic acid gas, and can live and thrive with little or no light. In green plants, which require the action of light, the intensity required is very different in different species; some require shady places, and hence the vegetable inhabitants of caves, and the plants which grow in the shade of forests; others, and the greater number, require the direct action of the sun, and grow in exposed elevated sites. De Candolle considers that the great difficulty of cultivating Alpine plants in the gardens of plains, arises from the impossibility of giving them at once the fresh temperature and intense light which they find on high mountains.

Sect. III. Civil Causes affecting the Distribution of Plants.

946. By the art of man plants may be inured to circumstances foreign to their usual habits. Though plants in general are limited to certain habitations destined for them by nature, yet some are, and probably the greater number may be, inured to climates, soils, and situations, of which they are not indigenous. The means used are acclimating and culture.

947. Acclimating seems to be most easily effected in going from a hot to a cold climate, particularly with herbaceous plants. Because it often happens that the frosts of winter are accompanied with snow, which shelters the plant from the inclemency of the atmosphere till the return of spring. Trees and shrubs, on the contrary, are acclimated with more difficulty, because they cannot be so easily sheltered from the colds, owing to the greater length of their stems and branches. The acclimating or naturalisation of vegetables is to be attempted by two modes: by sowing the seeds of successive generations, and by the difference of temperature produced by different aspects. The former is well exemplified in the case of the rice-plant which is grown in Germany, from seeds raised there, while if seeds from its native country, India, are used they will not vegetate (Sir J. Banks, in Hort. Trans. vol. i.); and the latter in the sloping banks of Professor Thouin of Paris, as described by Girardin. (Physiologie Vegetale, vol. i.) Some plants seem to have the capacity of vegetating in almost all climates, or of naturalising themselves in almost any. This is particularly the case with esculents, such as the domestic cabbages, potatoes, and carrots. (Dialogues on Botany, p. 411.)

948. Domesticated plants. "Some plants," Humboldt observes, "which constitute the object of gardening and of agriculture, have time out of mind accompanied man from one end of the globe to the other. In Europe, the vine followed the Greeks; the wheat, the Romans; and the cotton, the Arabs. In America the Tultiques carried with them the maize; the potato and the quinoa (Chenopodium quinoa, of which the seeds are used,) are found wherever have migrated the ancient Condinamareos. The migration of these plants is evident; but their first country is as little known as that of the different races of men, which have been found in all parts of the globe from the earliest traditions." (Geographie des Plantes, p. 25.)

949. The general effect of culture on plants is that of enlarging all their parts; but it often also alters their qualities, forms, and colors: it never, however, alters their primitive structure. "The potato," as Humboldt observes, "cultivated in Chili, at nearly twelve thousand feet above the level of the sea, carries the same flower as in Siberia."
950. The culinary vegetables of our gardens, compared with the same species in their wild state, afford striking proofs of the influence of culture on both the magnitude and qualities of plants. Nothing in regard to magnitude is more remarkable than in the case of the Brassica tribe; and nothing, in respect to quality, exceeds the change effected on the celery and carrot.

951. The influence of culture on fruits is not less remarkable. The peach, in its wild state in Media, is poisonous, but cultivated in the plains of Ispahan and Egypt, it becomes one of the most delicious of fruits. The effect of culture on the apple, pear, cherry, plum, and other fruits, is nearly as remarkable; for not only the fruits and leaves, but the general habits of the tree are altered in these and other species. The history of the migration of fruit-trees has been commenced by Sicker, in a work (Geschichte, &c.) which Humboldt has praised as equally curious and philosophical.

952. The influence of culture on plants of ornament is great in most species. The parts of all plants are enlarged, some are numerically increased, as in the case of double flowers; and what is most remarkable, even the colors are frequently changed, both in the leaf, flower, and fruit.

953. The influence of civilisation and culture, in increasing the number of plants in a country, is very considerable, and operates directly, by introducing new species for culture in gardens, fields, or timber-plantations; and indirectly by the acclimating and final naturalisation of many species, by the influence of winds and birds in scattering their seeds. The vine and the fig are not indigenous to France, but are now naturalised there by birds. In like manner the orange is naturalised in the south of Italy. Many herbaceous plants of the Levant are naturalised both in France and Britain; some, as the cabbage, cherry, and apple, were probably naturalised during the subjection of England to the Romans. The narrow-leaved elm was brought from the Holy Land during the crusades. Phaseolus vulgaris, and impatiens balsamina were brought originally from India; and datura stramonium, which is now naturalised in Europe, was brought originally from India or Abyssinia. Buckwheat and most species of corn and peas came also from the East, and along with them several plants found among corn only, such as centaurea cyanus, agrostemma githago, raphanus raphanistrum, and myagrum sativum. The country from whence the most valuable grasses migrated is not known. Bruce says he found the oat wild in Abyssinia, and wheat and millet have been found in a wild state in hilly situations in the East Indies. Rye and the potatoe were not known to the Romans. The country of the former Humboldt declares to be totally unknown.

954. The greatest refinement in culture consists in the successful formation of artificial climates for the culture of tropical plants in cold regions. Many vegetables, natives of the torrid zone, as the pine-apple, the palm, &c. cannot be acclimated in temperate countries. But by means of hot-houses of different kinds they are grown even on the borders of the frozen zone to the highest degree of perfection; and in Britain some of the tropical fruits, as the pine and melon, are brought to a greater size and better flavor than in their native habitations. Casting our eyes on man, and the effects of his industry, we see him spread on the plains and sides of mountains, from the frozen ocean to the equator, and everywhere he wishes to assemble around him whatever is useful and agreeable of his own or of other countries. The more difficulties to surmount, the more rapidly are developed the moral faculties; and thus the civilisation of a people is almost always in an inverse ratio with the fertility of the soil which they inhabit. What is the reason of this? Humboldt asks. Habit and the love of the site nativ.

Sect. IV. Characteristic or Picturesque Distribution of Vegetables.

955. The social and antisocial habits of plants is one of their most remarkable characteristics. Like animals they live in two classes: the one class grows alone and scattered, as solanum dulcamara, lychnis dioica, polygonum bistorta, anthericum liliago, &c. The other class unites in society, like ants or bees, covers immense surfaces, and excludes other species, such as fragaria vesca, vaccinium myrtillus, polygonum aviculare,aira canescens, pinus sylvestris, &c. Burton states that the Mitchella repens is the plant most extensively spread in North America, occupying all the ground between the 28th and 69th of north latitude. The arbutus uva ursi, extends from New Jersey to the 72nd of latitude. On the contrary, gordonia, franklinia, and dioeca muscipula are found isolated in small spots. Associated plants are more common in the temperate zones than in the tropics, where vegetation is less uniform and more picturesque. In the temperate zones, the frequency of social plants, and the culture of man, has rendered the aspect of the country comparatively monotonous. Under the tropics, on the contrary, all sorts of forms are united; thus cypressses and pines are found in the forests of the Andes of Quindiu, and of Mexico; and bananas, palms, and bamboos in the valleys. (fig. 69.) But green meadows and the season of spring are wanting in the south, for nature has reserved gifts for every region. "The valleys of the Andes," Humboldt observes, "are ornamented with bananas and palms; on the mountains are found oaks, firs, barberries, alders, brambles, and a
crowd of genera believed to belong only to countries of the north. Thus the inhabitant of the equinoctial regions views all the vegetable forms which nature has bestowed around him on the globe. Earth develops to his eyes a spectacle as varied as the azure vault of heaven, which conceals none of her constellations.” The people of Europe do not enjoy the same advantage. The languishing plants, which the love of science or luxury cultivates in our hot-houses, present only the shadow of the majesty of equinoctial vegetation; but by the richness of our language, we paint these countries to the imagination, and individual man feels a happiness peculiar to civilisation.

956. The features of many plants are so obvious and characteristic, as to strike every general observer. The scitamineae, tree-heaths, firs, and pines, mimosæ, climbers, cacti, grasses, lichens, mosses, palms, equitaceæ, arums, pothos, dracontium, &c. the chaffy-leaved plants, malvaeeæ, orchideæ, liliaceæ, &c. form remarkable groups distinguishable at first sight. Of these groups, the most beautiful are the palms, scitamineæ, and liliaceæ, which include the bamboos and plantains, the most splendid of unbranched plants.

957. The native countries of plants may often be discovered by their features in the same manner as the national distinctions which are observable in the looks and color of mankind, and which are effected chiefly by climate. Asiatic plants are remarkable for their superior beauty; African plants for their thick and succulent leaves, as in the case of the cacti; and American plants for the length and smoothness of their leaves, and for a sort of singularity in the shape of the flower and fruit. The flowers of European plants are but rarely beautiful, a great proportion of them being amentaceous. Plants indigenous to polar and mountainous regions are generally low, with small compressed leaves; but with flowers large in proportion. Plants indigenous to New Holland are distinguishable for small and dry leaves, that have often a shrivelled appearance. In Arabia they are low and dwarfish; in the Archipelago they are generally shrubby and furnished with prickles; while in the Canary Islands many plants, which in other countries are merely herbs, assume the port of shrubs and trees. The shrubby plants of the Cape of Good Hope and New Holland exhibit a striking similarity, as also the shrubs and trees of the northern parts of Asia and America, which may be exemplified in the platanus orientalis of the former, and in platanus occidentalis of the latter, as well as in fagus sylvatica and fagus latifolia, or acer cappadocium and acer saccharinum; and yet the herbs and under-shrubs of the two countries do not in the least correspond. “A tissue of fibres,” Humboldt observes, “more or less loose — vegetable colors more or less vivid, according to the chemical mixture of their elements, and the force of the solar rays, are some of the causes which impress on the vegetables of each zone their characteristic features.”

958. The influence of the general aspect of vegetation on the taste and imagination of a people — the difference in this respect between the monotonous oak and pine forests of the temperate zones, and the picturesque assemblages of palms, mimosas, plantains, and bamboos of the tropics — the influence of the nourishment, more or less stimulant, peculiar to different zones, on the character and energy of the passions: — these, Humboldt observes, unite the history of plants with the moral and political history of man.
### Sect. V. Systematic Distribution of Vegetables.

959. **The distribution of plants, considered in respect to their systematic classifications, is worthy of notice.** The three grand systematic divisions of plants are acotyledonea, dicotyledonea, and monocotyledonea. A simplification of this division considers plants as agamous, or phanerogamous, that is, without or with visible sexes.

960. **Plants of visible sexes.** Taking the globe in zones, the temperate contain $\frac{1}{6}$ part of all the phanerogamous or visible sexual species of plants. The equinoctial countries contain nearly $\frac{1}{6}$, and Lapland only $\frac{1}{4}$ part.

961. **Plants with the sexual parts invisible or indistinct.** Taking the whole surface of the globe, the agamous plants, that is, mosses, fungi, fuci, &c. are to the phanerogame or perfect plants, nearly as 1 to 7; in the equinoctial countries as 1 to 5; in the temperate zones as 2 to 5; in New Holland as 2 to 11; in France as 1 to 2; in Lapland, Greenland, Iceland, and Scotland, they are as 1 to 1, or even more numerous than the phanerogamous plants. Within the tropics, agamous plants grow only on the summits of the highest mountains. In several of the islands of the Gulf of Carpentaria, having a Flora of phanerogamous plants exceeding 200 species, R. Brown did not observe a single moss.

962. In the whole globe, the **monocotyledoneae**, including the grasses, liliaceae, scitamineae, &c. are to the whole of the perfect plants as 1 to 6; in the temperate zones (between 36° and 52°) as 1 to 4; and in the polar regions as 1 to 20. In Germany, the monocotyledoneae are to the total number of species as 1 to 4.5; in France as 1 to 4.7; in New Holland the three grand divisions of plants, beginning with the acotyledoneae, are nearly as 1, 24, and 71.

963. **Dicotyledoneae.** In the whole globe, the monocotyledoneae are estimated, by R. Brown, from Persoon’s Synopsis, (Gen. Rem. on the Bot. of Terr. Aust. 1814,) to be to the dicotyledoneae as 2 to 11; or with the addition of undescribed plants, as 2 to 9. From the equator to 30° of north latitude, they are as 1 to 5. In the higher latitudes a gradual diminution of dicotyledoneae takes place, until in about 60° north latitude and 50° south latitude they scarcely equal half their intertropical proportions. The ferns in the temperate regions are to the whole number of species as 1, 2, and 5; that is, in the polar regions as 1, in the temperate countries as 2, and in the intertropical regions as 5. In France, ferns form $\frac{1}{3}$ of the phanerogamous plants; in Germany $\frac{1}{12}$; in Lapland $\frac{1}{26}$.

964. **The natural orders of perfect or phanerogamous plants are variously distributed in different countries.** The following Table gives a general view of the relative proportions of several natural orders of perfect plants in France, Germany, and Lapland.

Three 3645 to 1884 to 497
965. The most universal plants are the agamous families. Their germs are the only ones which nature develops spontaneously in all climates. The polystachium commune (fig. 70.) grows in all latitudes; in Europe and under the equator; on high mountains and on a level with the sea; in short, wherever there is shade and humidity. No phanerogamous plants have organs sufficiently flexible to accommodate themselves in this manner to every zone. The alpine media, fragaria vesca, and solanum nigrum, have been supposed to enjoy this advantage; but all that can be said is, that these plants are very much spread, like the people of the race of Caucasus, in the northern part of the ancient continent. (Humboldt.)

Sect. VI. Economical Distribution of Vegetables.

966. The plants chiefly employed in human economy differ in different climates and countries; but some, as the cereal grasses, are in universal use; and others, as the banana and planain (fig. 71.), only in the countries which produce them.

967. The bread-corn of the temperate climates is chiefly wheat and maize; of the hot climates rice, and of the coldest climates barley.

968. The edible roots of the old world are chiefly the yam, sweet potatoe, onion, carrot, and turnip; of the new the potatoe.

969. The oleaceous herbs of temperate climates are chiefly the brassica family, and other cruciferae. In hot climates pot-herbs are little used. Legumes, as the pea, bean, and kidney-bean, are in general use in most parts of the old world.

970. The fruits of the northern hemisphere belong chiefly to the orders of Pomaceae, Amygdalineae, Grossulariae, Rosaceae, Viticeae, and Amelaceae.

The fruits of the East Indies belong chiefly to Myrtaceae, Guttiferae, Aurantae, Musaceae, Palmae, Cucurbitaceae, Myristiceae, &c.

The fruits of China are chiefly of the orders of Aurantae, Myrtaceae, Rhamnaceae, Pomaceae, Amygdalinea, Palmae, &c.

The fruits of Africa belong to Sapoteae, Palmae, Chrysobalanaceae, Guttiferae, Apocineae, Papilionaceae, Musaceae, and Cucurbitaceae.

The fruits of South America belong to Annonaceae, Myrtaceae, Terebintaceae, Myristiceae, Palmae, Bromeliaceae, Sapoteae, Laurineae, Chrysobalanaceae, Musaceae, Papilionaceae, and Passiflorceae.

971. The most showy herbaceous flowers of the temperate zone belong to Rosaceae, Lilieae, Irideae, Eriocaceae, Ranunculaceae, Primulaceae, Caryophyllaceae, Gentianeae, &c. Those of the torrid zone belong to the Scitamineae, Amaryllideae, Bignoniaceae, Mela-stomaceae, Magnoliaceae, Papilionaceae, Apocineae, &c.

The most useful timber-trees of temperate climates are of the pine or fir kind; of warm climates the palm and bamboo. The universal agricultural order is the Gramineae.

Sect. VII. Arithmetical Distribution of Vegetables.

972. The total number of species of plants known, or believed to exist, amounts to about 44,000, of which 38,000 have been described. According to Humboldt and R. Brown, they are thus distributed: in Europe 7000; in temperate Asia 1500; in equinoctial Asia and the adjacent islands 4500; in Africa 3000; in temperate America, in both hemispheres, 4000; in equinoctial America 13,000; in New Holland and the islands of the Pacific Ocean 5000; in all 38,000. In Spitzbergen there are 30 species of perfect plants; in Lapland 534; in Iceland 533; in Sweden 1299; in Scotland 900; in Britain 1400; in Brandenburg 2000; in Piedmont 2800; in Jamaica, Madagascar, and the coast of Coromandel, from 4000 to 5000.

Sect. VIII. Distribution of the British Flora, indigenous and exotic.

973. About thirteen thousand plants compose the Hortus Britannicus, or such species as admit of cultivation. Mosses, Fungi, Fuci, Algae, and Lichens are, with a few exceptions, excluded.
DISTRIBUTION OF THE BRITISH FLORA.

974. The natives of Britain which enter into this Hortus are upwards of 1400 species; but the native British Flora contains in all above 3300 species. Of these there are about 1437 cotyledonous plants, and nearly 1893 of imperfect, or of what are termed, in the Jussieuian system, acotyledoneae.

975. Of the cotyledonous or perfect plants, 182 are trees or shrubs; 835 are perennials; 60 are biennials, and 340 annuals. Of the trees and shrubs, 47 are trees; 25 above thirty feet high, and the remainder under thirty, but above 10 feet high. Of the perennials 83 are grasses; the next greatest number belong to the two first orders of the class Pentandria; the next to the Syngenesia; and the third to Monoea Triandria, or the Cyperaceae of Jussieu, comprehending chiefly the genus Carex. Most of the biennials belong to the first order of the 19th class, and the two first orders of Pentandria. There are 41 annual grasses; 52 annuals belong to the two first orders of Pentandria; and the next greatest number of annuals to Diadelphia Decandria, which includes the trefoils and vetches.

976. Of the Cryptogameae, or imperfect plants, 800 are fungi; 18 algae; 373 lichens; 85 hepaticæ; 460 musci; and 130 ferns; according to an estimate (in Rees’s Cyclop. art. Plant.) understood to be made by Sir J. E. Smith.

977. In regard to the distribution of the perfect plants as to elevation, little or nothing has been yet generalised on the subject. In regard to soils, 276 are found in bogs, and marshy or moist places; 140 on the sea-shores; 128 in cultivated grounds; 121 in meadows and pastures; 78 in sandy grounds; 76 in hedges and on hedge-banks; 70 on chalky and other calcareous soils; 64 on heaths; 60 in woods; 30 on walls; 29 on rocks; and 19 on salt-marshes; — reckoning from Galpin’s Compend. Fl. Brit.

978. In the distribution of the Cryptogameae, the ferns prevail in rocky places and wastes; most of the musci, hepatici, and lichens, on rocks and trees; most of the fuci and algae in the sea; and of the fungi, on decaying vegetable bodies, especially trunks of trees, manures, &c.

979. In respect to geographical distribution, the mountainous and hilly districts of England and South Wales are most prolific; the greatest number, according to extent of surface, are found in England and Wales, and the smallest number in Ireland.

980. The genera of the native British Flora have been already arranged according to the Linnaean and Jussieuian systems (where they are distinguished by marks *); they enter into 23 classes and 71 orders of the former, and 8 classes and 121 orders of the latter system.

981. With respect to the uses or application of the native Flora, there are about 18 sorts of wild fruits which may be eaten, exclusive of the wild apple and pear; but only the pear, apple, plum, currant, raspberry, strawberry, and cranberry, are gathered wild, or cultivated in gardens. There are about 20 boiling culinary plants natives, including the cabbage, sea-kale, asparagus, turnip, carrot, and parsnip. There are about the same number of spinaceous plants, salading, and pot and sweet herbs, which may be used, but of which but a few only enter into the dietetics of modern cooks. There are three fungi, in general use, the mushroom, truffle, and morel; and various others, as well as about eight species of sea-weeds, are occasionally eaten. There are about six native plants cultivated as florists’ flowers, including the primula elatior, crocus, narcissus, dianthus, &c. Nearly 100 grasses, clovers, and leguminous plants are used in agriculture, or serve in their native places of growth as pasturage for cattle. Two native plants, the oat and the big, or wild barley, are cultivated as farmaceous grains. Most of the trees are used in the mechanical arts, for fuel, or for tanning: one plant, the flax, not an aboriginal native, but now naturalised, affords fibre for the manufacture of linen cloth. Various plants yield colored juices, which may be, and in part are, used in dyeing; and some hundred species have been, and a few are still used in medicine. About 20 cotyledonous plants, and above 50 cryptogameae, chiefly fungi, are, or are reputed to be, poisonous, both to men and cattle.

982. By the artificial Flora of Britain, we understand such of the native plants as admit of preservation or culture in gardens; and such exotics as are grown there, whether in the open ground, or in different descriptions of plant habitations. The total number of species which compose this Flora, or Hortus Britannicus, as taken from Sweet’s catalogue, is, as already observed (973.), about 13,000, including botanists’ varieties, and excluding agamous plants. This is nearly a fourth part of the estimated Flora of our globe, and may be considered in regard to the countries from whence the plants were introduced; the periods of their introduction; their obvious divisions; their systematic classification; their garden habitations; their application; and their native habitations.

983. With respect to the native countries of the artificial Flora or Hortus Britannicus, of 970 species the native countries are unknown; the remaining 12,000 species were first introduced from the following countries: —
984. With respect to the dates of the introduction of the exotics from those different countries, the dates of the introduction of none are known before the time of Gerard, in Henry VIII's reign. From this author & Trew, it appears that 47 species were introduced on or before 1548, including the apricot, fig, pomegranate, &c. Those previously introduced, of which the dates are unknown, may be considered as left here by the Romans, or afterwards brought over from France, Italy, and Spain, by the ecclesiastics, and preserved in the gardens of the religious houses. Henry died in 1547; but the plants introduced in the year after his death, may be considered as properly belonging to his reign.

985. With respect to the obvious character of the artificial Flora, 350 species are hardy trees or shrubs; of these 270 are trees above 10, and 100 trees above 30 feet high. Of these, the larch, spruce fir, silver fir, and Lombardy poplar, sometimes attain the height of 100 feet. Above 400 species are hardy grasses. Of the tender exotics, the greater number are trees or shrubs, and the next greatest number annuals and bulbs. The colors of the blossoms are generally rich and vivid in proportion to the warmth of the climate of which the plants are natives.

986. In regard to systematic and horticultural distribution, the following Table gives a combined view of the whole, arranged according to the Linnaean system, and also according to their habitation in the garden.

</table>
988. *The uses of these arrangements,* and of the other tables in this chapter to the botanist and cultivator, are very considerable. They afford a full view of the riches of the British garden; a condensed view of the affinities of plants, by which their properties, culture, and alliances by grafting, crossing, &c. may be estimated; and the means of selecting plants for every department of the garden. Thus, a person wishing to possess a collection of hardy plants, may, from the two last tables, order a certain number of annuals, biennials, perennials, and trees from each of the Linnaean or Jussieuian classes. Or if he wishes merely a few species of dried plants to illustrate each of the classes or orders of these systems, he may give instructions for forming a herbarium from the tables of the genera before given. (588, 589.) He may there also make a choice for any purpose confined to British plants. To the gardener these tables will be particularly useful, by enabling him to form arrangements in any of the departments of culture with ease and effect. Thus, supposing he is desirous of arranging his green-house plants according to the method of Jussieu; then, beginning, say with Ranunculaceae, he finds that order contains only one tree and two perennials which are green-house plants; on turning to the Jussieuian classification of the genera (589.), he finds Atragene and Knowltonia furnish these. If these genera are in his collection, he begins by placing them together. Next, he proceeds to Magnoliaceae, in which there are three green-house trees, and so on;—proceeding thus, whether in arranging hardy, green-house, or hot-house plants in the natural method, and similarly, if arranging them according to that of Linnaeus. It is proper to observe, that though great care has been taken to attain arithmetical correctness in these tables, yet, in some cases, we have failed of perfect success; but as the number of plants in the artificial Flora is every day increasing, and their arrangement and even names very frequently varying, there is no occasion for absolute perfection in arithmetical enumerations for subjects such as ours, and even a much less degree than what has been attained would have answered the purpose equally well.

989. *Purchasable British Flora.* The whole of the plants enumerated as forming the British Flora, are probably not at any one time all in existence in Britain. Many of them, especially the exotic species, which were introduced at Kew, have been lost there through accidents or diseases, and are wanting for a time till new seeds or plants are obtained from abroad. Had they been distributed among the nurserymen they would have been abundantly multiplied and spread over the country. Casualties happen even to hardy plants, and a species which at one time is to be found in moderate quantities in the nurseries is at another period comparatively scarce. Thus, if we reduce the actual number of species to be found in cultivation at one time to from 9000 to 10,000, it will be found nearer the truth. In the public nurseries, varieties are very much cultivated, in order, as it were, to place the beauties of esteemed species in different points of view; or to produce in vegetables something analogous to what are called variations in musical compositions. The following may be considered as a popular or horticultural distribution of the species and varieties obtainable from British nurseries. It is taken from a catalogue entitled *Prodromus,* &c.; or Forerunner of the collection in Page’s Southampton nursery-garden, drawn up by L. Kennedy, (late of the Hammersmith nursery,) and published in 1818. It is a work of great practical utility, and with Sweet’s *Hortus,* should be in the hands of every gardener who has a collection of plants under his care.

Proteas | 120 | Bulbous-rooted plants | 500 |

992. Hot-house Plants.

---|---|---
Trees and shrubs | 830 | Aquatics | 28 | Hardy | 80
Climbers | 150 | Reedy or scianumious | 55 | Half hardy | 80
Succulents | 130 | 
Bulbous-rooted plants | 80 | 
Herbaceous | 170 |

993. Annuals, native and exotic.

---|---|---
Hardy | 500 | Used in agriculture exclusive of grasses | 80 |
Half hardy | 110 | 
Tender | 100 | 
Esculent | 900 |

Total. Hardy, 4580; green-house and dry-stove, 3180; hot-house, 1463; annuals, 820; total, 10,043; of these, above 3000 may be considered as varieties, so that the actual hortus procurable in British nurseries, may be estimated, as to the British hortus of books, as 7 to 12, or including the cryptogamous plants, as 8 to 12.

994. With respect to the application of the purchasable Flora of Britain, including species and varieties, we submit the following as only a rude outline, the subject not admitting of perfect accuracy from the ever-varying number of varieties.

995. Varieties of Fruit-trees, and Fruit-bearing Plants, for Sale in British Nurseries.

---|---|---
Apples | 500 | Apricots | 60 | Cranberry | 1 |
Pears | 300 | Plums | 150 | Mulberries | 2 |
Medlars | 2 | Cherries | 50 | Filter | 6 |
Quinces | 2 | Grapes | 30 | Walnuts | 5 |
Services | 3 | Figs | 200 | Chestnuts | 5 |
Greengrave and Lemons | 60 | Gooseberries | 4 | Melons | 15 |
Peaches | 100 | Currants | 10 | Pine-apples | 20 |
Nectarines | 20 | Raspberries | 30 |
Almonds | 6 | Strawberries | 50 |

Total 1147

996. Exscent Hiberoose Plants, annuals and perennials, used in Horticulture.

---|---|---
Cabbage tribe | 55 | Pot-herbs and garnishings | 15 |
Leguminous plants | 3 | Sweet herbs | 12 |
Succulent roots | 45 | Plants used in confectionary | 14 |
Sulphuraceous plants | 10 | and domestic medicine | 18 |
Allaceous plants | 18 | Plants used as preserves | 12 |
Asparagusaceous plants | 11 | and pickles | 26 |
Acetaceceous plants | 25 | Total | 161 337 |

997. Florists' Flowers, used in Floriculture.

---|---|---
Bulbous-rooted Plants | 500 | Colchicums | 100 | Tuberous-rooted Plants | 300 |
Hyacinths | 200 | Other sorts | 100 | Dahlias | 400 |
Tulips | 500 | Fibrous-rooted Plants | 30 |
Poppies | 100 |
Crocus | 100 | Amaryllis | 200 |
Narcissi | 200 | Ranunculuses | 300 |
Iris | 100 | Anemones | 200 |
Fritillaries | 20 | Total | 2666 |
Grapes | 20 |
Crown-imperials | 6 | Carnations | 300 |
Dianthus | 6 |
Dahlias | 400 |

Total 530

998. Hardy Timber-trees and Shrubs, used in Arboriculture, Floriculture, and Landscape-gardening.

---|---|---
Trees planted for timber | 100 | Shrubs planted for various uses, as fuel, charcoal, bark, firewood, &c. | 30 |
Other useful purposes | 20 | 
Trees planted for ornament | 100 |
Hedge-plants | 10 |

Total 530

999. Agricultural Hiberoose Plants, grown for Food for Men and Cattle, and for use in various Arts.

---|---|---
Grains for human food | 50 | Plants used for drying | 2 |
Leguminous seeds | 10 | Plants used for the clothing arts | 2 |
Roots | 60 | Sea-plants | 6 |
Herbage plants, not grasses | 90 | Mosse used in drying | 1 |
Grasses, and grasses for the inferior animals | 25 | for various purposes in the arts | 6 |
Plants used for furnishing oils and essences | 5 |

Total 65 112

1000. Miscellaneous applications of Hardy Perennials, native and exotic.

---|---|---
Border-flowers, or such as are used in flower-gardens and shrubberies, in ordinary cases about | 500 | Used for distillation and parfumery | 30 |
Used in the modern pharmacopœia | 50 | 
Sold by herbists, and used by quacks and irregular practitioners | 20 |

Total 870

1001. Application of curious Hot-house Exotics, or such plants of ornamental as require the protection of glass. Of these there are in ordinary green-houses seldom more than 100 species and varieties, and not more than half that number in most of our plant-stoves. The remainder of this class are confined to the public and private botanic gardens, and to eminent...
public nurseries. Many of this division are of great importance in their native countries, as the indigo, sugar-cane, tea-tree, cinnamon, &c.; the mango, durion, and other excellent fruits, the palms, bamboo, &c. Even some here treated as entirely ornamental, afford useful products in their own countries, as the camellia, sun-flower, &c., from the seeds of which oils are expressed in China and America. The cultivation or preservation of living specimens of these plants, therefore, in our green-houses and stoves, is a rational entertainment, and also useful, as many species become in time acclimated, and some even naturalised; and uses may in time also be discovered for such as are now merely looked on as objects of curiosity. But it is quite enough to justify much more than all the care that is taken to obtain and preserve them, that they contribute to elegant enjoyment; for what is life when it does not exceed mere obedience to the animal instincts?

1002. With respect to the native habitations of the exotic part of the Hortus Britannicus, little can be advanced with certainty. In general it seems to appear that moist and moderately warm climates, and irregular surfaces, are most prolific in species; and judging of the whole world from Europe, we should venture to consider half the species of plants in existence as growing in soft and rather moist grounds, whether low or elevated. The soil of surfaces constantly moist, or inclining to be moist, whether watered from the atmosphere or from subterraneous sources, is almost always found to be minutely divided, and generally of a black vegetable or peaty nature. Immense tracts in Russia and America are of this description, and even when dry, resist evaporation better than any other. In such soils, the roots of plants are generally small and finely divided, as in the heaths, most bog plants, and nearly all the American shrubs. The next sort of habitations most prolific in species, appears to us to be arenaceous soils in temperate climates, and in proportion to their moisture. Here the roots of plants are also small, but less so than in soils of the former description. On rocky and calcareous soils the roots of plants are generally strong and woody, or at least long and penetrating. In clayey habitations, exclusive of the alluvial depositions of rivers, few plants are found, and these generally grasses, or strong fibrous-rooted herbaceous plants, or tap-rooted trees. Such at least is the amount of our generalisations; but as our observation has been limited to Europe, and does not even extend to the whole of it, those who have visited Africa and Asia are much more capable of illustrating the subject. One conclusion we think the cultivator is fully entitled to draw, that the greater number of plants, native or foreign, will thrive best in light soil, such as a mixture of soft black vegetable mould or peat and fine sand kept moderately moist; and that on receiving unknown plants or seeds, of the native sites of which he is ignorant, he will err on the safe side by placing them in such soils rather than in any other; avoiding, most of all, clayey and highly manured soils, as only fit for certain kinds of plants constitutionally robust, or suited to become monstrous by culture.

CHAP. XI.

Origin of Culture, as derived from the Study of Vegetables.

1005. Agriculture and gardening are the two arts which embrace the whole business of cultivating vegetables, for whatever purpose they are applied by civilised man, and in this respect their fundamental principles are the same; they are all indicated by nature, and explained by vegetable chemistry and physiology.

1004. The object of vegetable culture is either to increase the number of plants; to increase their number and retain their native qualities; to increase their number and improve their qualities; to increase their magnitude; to increase their number, improve the quality, and increase the magnitude of particular parts of the vegetable; to form new varieties for the furtherance of all or any of the above purposes; to propagate and preserve from degenerating approved varieties of vegetables; and to preserve vegetables for future use.

The first step, for all these objects in common, is to procure the desired plant, either by removing it in an entire state from its native site, and planting it in an appropriate situation; or by gathering and sowing its seeds; or by propagating from a part of the plant. Hence the general origin both of agriculture and gardening, and of all the different modes of propagation, transplanting, and collecting seeds.

The next step is to secure the plants to be cultivated from the depredations of animals, or unsuitable weather, either by surrounding them with an adequate barrier where they are growing fortuitously, or by removing them to a spot already protected. Hence the origin of fences and enclosures, and plant habitations.

A third step common to all the above objects of culture is to remove from the vicinity of the plant to be cultivated, or from the plant itself, all other plants, or animals, or objects likely to impede its progress. Hence the origin of weeding, thinning, destroying insects, and curing diseases.

1005. To increase the number and retain the native qualities of vegetables, it is necessary to imitate, as exactly as circumstances will admit, their native habitation, in respect to soil, climate, mode of watering, light, &c. If the habitation is in any way ameliorated, the qualities of the plant will be altered, and its parts enlarged, which is not desired.
All that is necessary, therefore, for effecting this branch of culture, is to imitate the habit-
atation, and to propagate. This is, or ought to be the case, wherever plants are grown for
medical or botanical purposes, as in herb and botanic gardens. Nature is here imitated
as exactly as possible, and the result is productions resembling, as near as possible, those
of nature.

1006. To increase the number and improve the qualities of plants, it is necessary to facili-
tate their mode of nutrition by removing all obstacles to the progress of the plant.
These obstacles may either exist under or above the surface; and hence the origin of drain-
ing, clearing from surface-incumbrances, and the various operations, as digging, plough-
ing; &c. for pulverising the soil. Nature suggests this in accidental ruptures of the
surface, broken banks, the alluvial depositions from overflowing rivers, and the earth
thrown up by underground animals. Many of the vegetables within the influence of
such accidents are destroyed, but such as remain are ameliorated in quality, and the reason
is, their food is increased, because their roots, being enabled to take a more extensive
range, more is brought within their reach.

1007. It is necessary, or at least advantageous, to supply food artificially; and hence the
origin of manuring. All organised matters are capable of being converted into the food
of plants; but the best manure for ameliorating the quality, and yet retaining the peculiar
chemical properties of plants, must necessarily be decayed plants of their own species.
It is true that plants do not differ greatly in their primary principles, and that a supply
of any description of putrescent manure will cause all plants to thrive; but some plants,
as wheat, contain peculiar substances, (as gluten and phosphate of lime,) and some ma-
tures, as those of animals, or decayed wheat, containing the same substances, must neces-
sarily be a better food or manure for such plants. Manuring is an obvious imitation of
nature, every where observable by the decaying herbage of herbaceous plants, or the fal-
len leaves of trees, rotting into dust or vegetable mould about their roots; and by the
effect of the dung left by pasturing or other animals.

1008. Amelioration of climate is farther advantageous, in improving the qualities of vege-
tables, by increasing or diminishing its temperature according to the nature of the plant;
unless, indeed, it be situated in a climate which experience and observation show to be
exactly suited to its nature. Hence the origin of shelter and shade, by means of walls,
hedges, or strips of plantation; of sloping surfaces or banks, to receive more directly or
indirectly the rays of the sun; of soils better calculated to absorb and retain heat; walls
fully exposed to the south, or to the north; of training or spreading out the branches of
trees on these walls; of hot-walls; of hot-beds; and finally of all the variety of hot-houses.
Nature suggests this part of culture, by presenting, in every country, different degrees of
shelter, shade, and surface, and in every zone different climates.

1009. The regulation of moisture is the next point demanding attention; for when the
soil is pulverised, it is more easily dried by the penetration of the air; when an increase
of food is supplied, the medium through which that food is taken up by the plant should
be increased; and when the temperature is increased, evaporation becomes greater.
Hence the origin of watering by surface or subterranean irrigation, manual supplies to
the root, showering over the leaves, steaming the surrounding atmosphere, &c. This
is only to imitate the dews and showers, streams and floods of nature; and it is to be re-
gretted that the imitation is in most countries attended with so much labor, and requires
so much nicety in the arrangement of the means, and judgment in the application of
the water, that it is but very partially applied by man in every part of the world, excepting
perhaps a small district of Italy. But moisture may be excessive; and on certain soils at
certain seasons, and on certain productions at particular periods of their progress, it may
be necessary to carry off a great part of the natural moisture, rather than let it sink into
the earth, or draw it off where it has sunk in and injuriously accumulated, or prevent its
falling on the crop at all; and hence the origin of surface-drainage by ridges, and of un-
der-draining by covered conduits, or gutters; and of awnings and other covers to keep off
the rain or dews from ripe fruits, seeds, or rare flowers.

1010. The regulation of light is the remaining point. Light sometimes requires to be ex-
cluded and sometimes to be increased, in order to improve the qualities of vegetables;
and hence the origin of thinning the leaves which overshadow fruits and flowers, the
practice of shading cuttings, seeds, &c., and the practice of blanching. The latter
practice is derived from accidents observable among vegetables in a wild state, and its in-
fluence on their quality is physiologically accounted for by the obstruction of perspiration,
and the prevention of the chemical changes effected by light on the epidermis.

1011. Increasing the magnitude of vegetables, without reference to their quality, is to be
obtained by an increased supply of all the ingredients of food, distributed in such a body
of well pulverised soil as the roots can reach to; of heat and moisture; of a partial ex-
clusion of the direct rays of the sun, so as to moderate perspiration; and of wind, so as to
prevent sudden desiccation. But experience alone can determine what plants are best
suited for this, and to what extent the practice can be carried. Nature gives the hint in
the occasional luxuriance of plants accidentally placed in favorable circumstances, and man adopts it, and improving on it, produces cabbages and turnips of half a cwt.; apples of one pound and a half; and cabbage-roses of four inches in diameter; productions which may in some respects be considered as diseased.

1012. To increase the number, improve the quality, and increase the magnitude of particular parts of vegetables. It is necessary, in this case, to remove such parts of the vegetable as are not wanted, as the blooms of bulbous or tuberous rooted plants, when the bulbs are to be increased, and the contrary; the water-shoots and leaf-buds of fruit-trees; the flower-stems of tobacco; the male flowers and barren runners of the cucumis tribe, &c. Hence the important operations of pruning, ringing, cutting off large roots, and other practices for improving fruits and throwing trees into a bearing state. At first sight these practices do not appear to be copied from nature; but, independently of accidents by fire, already mentioned, which both prune and manure, and of fruit-bearing trees, say thorns or oaks, partially blown out by the roots, or washed out of the soil by torrents, which always bear better afterwards, why may not the necessity that man was under, in a primitive state of society, of cutting or breaking off branches of trees, to form huts, fences, or fires, and the consequent vigorous shoots produced from the parts where the amputation took place, or the larger fruit on that part of the tree which remained, have given the first idea of pruning, cutting off roots, &c. It may be said that this is not nature but art; but man, though an improving animal, is still in a state of nature, and all his practices, in every stage of civilisation, are as natural to him as those of the other animals are to them. Cottages and palaces are as much natural objects as the nests of birds, or the burrows of quadrupeds; and all the laws and institutions by which social man is guided in his morals and politics, are no more artificial than the instinct which congregates sheep and cattle in fields and herds, and guides them in their choice of pasturage and shelter.

1013. To form new varieties of vegetables, as well as of flowers and useful plants of every description, it is necessary to take advantage of their sexual differences, and to operate in a manner analogous to crossing the breed in animals. Hence the origin of new sorts of fruits. Even this practice is but an imitation of what takes place in nature by the agency of bees and other insects, and the wind; all the difference is, that man operates with a particular end in view, and selects individuals possessing the particular properties which he wishes to perpetuate or improve. New varieties, or rather subvarieties, are formed by altering the habits of plants; by dwarfing through want of nourishment; variegating by arenarious soils; giving or rather continuing peculiar habits when formed by nature, as in propagating from monstrosities — fasciculi of shoots, weeping shoots, shoots with peculiar leaves, flowers, fruit, &c.

1014. To propagate and preserve from degeneracy approved varieties of vegetables, it is in general necessary to have recourse to the different modes of propagating by extension. Thus choice apples and tree fruits are preserved and multiplied by grafting; others, as the pine-apple by cuttings or suckers; choice carnations by layers, potatoes by cuttings of the tubers, &c. But approved varieties of annuals are in general multiplied and preserved by selecting seed from the finest specimens and paying particular attention to supply suitable culture. This part of culture is the farthest removed from nature; yet there are notwithstanding examples of the fortuitous graft; of accidental layers; of leaves, or detached portions, forming natural cuttings, (as of the cardamine hirsuta,) dropping and taking root.

1015. The preservation of vegetables for future use is effected by destroying or rendering dormant the principle of life, and by warding off, as far as practicable, the progress of chemical decomposition. Hence some vegetables are dried, and either their herbs, or roots, or fruits; others are placed beyond the reach of the active principles of vegetation, heat, and moisture, as seeds, cuttings, scions, roots, and fruits; and some are, in addition, even excluded from air, or placed in very low temperatures. The origin of these practices are all obvious imitations of what accidentally takes place in nature, from the withered grassy tressock to the hedgehog's winter store; and hence the origin of herb, seed, fruit, and root rooms and cellars, and packing plants and seeds for sending to a distance.

1016. The whole of gardening, as an art of culture, is but a varied development of the above fundamental practices, all founded in nature, and for the most part rationally and satisfactorily explained on chemical and physiological principles. Hence the great necessity of the study of botany to the cultivator, not in the limited sense in which the term is often taken as including mere nomenclature and classification, but in that extended signification in which we have here endeavored, proportionately to our limited space, to present the study of the vegetable kingdom. Those who would enter more minutely into the subject will have recourse to the excellent work of Keith, from whom we have quoted at such length; to Sir J. E. Smith's Introduction; and to the elementary works of Willdenow and De Candolle.
BOOK II.

OF THE NATURAL AGENTS OF VEGETABLE GROWTH AND CULTURE.

1017. The phenomena of vegetation being examined, and the facts ascertained that plants derive their nourishment from the external elements of matter: the next step in the study of the science of gardening is to enquire into the composition and nature of material bodies, and the laws of their changes. The earthy matters which compose the surface of the earth, the air and light of the atmosphere, the water precipitated from it, the heat or cold produced by the alternation of day and night, and by chemical composition and resolution, must include all the elements concerned in vegetation. These elements have all been necessarily brought into notice in the study of the vegetable kingdom; but we shall now examine more minutely their properties, in so far as they are connected with cultivation. To study them completely, reference must be had to systems of chemistry and mechanical philosophy, of which those of Dr. Thomson (System of Chemistry) and Dr. Young (Lectures on Mechanical Philosophy) may be especially recommended.

CHAP. I.

Of Earths and Soils.

1018. Earths are the productions of the rocks which are exposed on the surface of the globe, and soils are earths mixed with more or less of the decomposed organised matter afforded by dead plants and animals. Earths and soils, therefore, must be as various as the rocks which produce them, and hence to understand their nature and formation it is necessary to begin by considering the geological structure of the territorial surface, and the manner in which earths and soils are produced; and we shall next consider in succession the nomenclature, quality, use, and improvement of soils.

1019. The crust, or under surface of the earth, is considered by geologists as presenting four distinct series of rocky substances; the first, supposed to be coeval with the world, are called primitive, and consist chiefly of granite and marble, below which man has not yet penetrated. The second series, called by the Wernerians transition-rocks, are of more recent formation, and seem to have resulted from some great catastrophe, (probably that to which history gives the name of deluge,) tearing up and modifying the former order of things. Clay-slate is one of the principal rocks of this class, and next limestone, sandstone, and trap or whinstone. The third series are called secondary rocks, and seem to owe their formation to partial or local revolutions, as indicated by their comparatively soft and fragile structure, superincumbent situation, and nearly horizontal position. They are chiefly limestones, sandstones, and conglomerations of fragments of other rocks, as plum-pudding-stone, &c. and appear rather as mechanical deposits from water than as chemical compounds from fusion or solution. A fourth stratum consists of alluvial or earthy depositions from water, in the form chiefly of immense beds of clays, marls, or sands. These strata are far from being regular in any one circumstance; sometimes one or more of the strata are wanting, at other times the order of their disposition seems partially inverted; their continuity of surface is continually interrupted, so that a section of the earth almost everywhere exhibits only confusion and disorder to persons who have not made geology more or less their study.

1020. The succession of alluvial, secondary, transition, and primary strata, in England, has been illustrated by Professor Brande (Outlines of Geology), by two sections, supposed to be taken through them.

1021. The first section (fig. 72.) commences with the blue clay of London (1), and proceeding westward through the counties of Berkshire, Hampshire, Wiltshire, Dorsetshire, and Devonshire, terminates at the Land's End, in Cornwall. The rocks and earths presented in this line are, the Windsor alluvion (2), Hampshire and Salisbury chalk (3), alluvion (4), sandstone (5), alluvion (6), Sherborne freestone (7), sandstone (8), blue lias limestone (9), Blackdown sandstone (10), Devonshire red sandstone (11), mountain limestone (12), Dartmoor slate (13), granite (14), slate again (15), greenstone (16), Cornwall serpentine (17), slate killas (18), Cornwall granite (19), slate killas (20), and finally, Cornwall granite.
1022. The second section (fig. 73.) commences with the coal strata, and limestone resting upon slate and granite in Cumberland, and thence proceeds towards the metropolis by Yorkshire, Derbyshire, Leicestershire, Northamptonshire, Bedfordshire, and Hertfordshire. The passage is here exhibited from the primary rocks of Cumberland to the secondary hills of the southern counties. It shows the Cumberland coal (a), limestone and slate (b), the Mosdale granite (c), slate (d), grauwacke (e), Ribblesdale limestone (f), gritstone (g), Ashton coal (h), Derby limestone (i), Derby toadstone (k), gritstone (l), gypsum (m), sandstone (n), limestone (o), Charnwood slate (p), Mountsorrel granite (q), red sandstone (r), lias limestone (s), Northampton oolite or freestone (t), Woburn sand (u), Dunstable chalk (v), and terminates in the London clay (w), with which the first section sets out.

1023. The surface earth, or that which forms the outer coating of the dry parts of the globe, is formed by the detritus or worn off parts of rocks and rocky substances. For in some places, as in chasms and vacuities between rocky layers or masses, earth occupies many feet in depth, and in others, as on the summits of chalk hills or granite mountains, it hardly covers the surface.

1024. Earths are, therefore, variously composed, according to the rocks or strata which have supplied their particles. Sometimes they are chiefly formed from slate-rocks, as in blue clays; at other times from sandstone, as in siliceous soils; and mostly of a mixture of clayey, slaty, and limestone rocks, blended in proportions as various as their situations. Such we may suppose to have been the state of the surface of the dry part of the globe immediately after the last disruption of its crust; but in process of time the decay of vegetables and animals form additions to the outer surface of the earths, and constitute what are called soils; the difference between which and earths is, that the former always contain a portion of vegetable or animal matter.

1025. The manner in which rocks are converted into soils, Sir H. Davy observes (Elem. of Agric. Chem. 188.), may be easily conceived by referring to the instance of soft granite, or porcelain granite. This substance consists of three ingredients, quartz, feldspar, and mica. The quartz is almost pure siliceous earth in a crystalline form. The feldspar and mica are very compounded substances; both contain silica, alumina, and oxide of iron; in the feldspar there is usually lime and potassa; in the mica, lime and magnesia. When a granitic rock of this kind has been long exposed to the influence of air and water, the lime and the potassa contained in its constituent parts are acted upon by water or carbonic acid; and the oxide of iron, which is almost always in its least oxidised state, tends to combine with more oxygen; the consequence is, that the feldspar decomposes, and likewise the mica; but the first the most rapidly. The feldspar, which is as it were the cement of the stone, forms a fine clay: the mica partially decomposed mixes with it as sand; and the undecomposed quartz appears as gravel, or sand of different degrees of fineness. As soon as the smallest layer of earth is formed on the surface of a rock, the seeds of lichens, mosses, and other imperfect vegetables which are constantly floating in the atmosphere, and which have made it their resting-place, begin to vegetate; their death, decomposition, and decay afford a certain quantity of organizable matter, which mixes with the earthy materials of the rock; in this improved soil more perfect plants are capable of subsisting; these in their turn absorb nourishment from water and the atmosphere; and, after perishing, afford new materials to those already provided: the decomposition of the rock still continues; and at length, by such slow and gradual processes, a soil is formed in which even forest-trees can fix their roots, and which is fitted to reward the labors of the cultivator.

1026. The formation of peaty soils is produced from very opposite causes, and it is interesting to contemplate how the same effect may be produced by different means, and the earth which supplies almost all our wants may become barren alike from the excessive application of art, or the utter neglect of it. Continuous pulverisation and cropping without manuring will certainly produce a barren barren soil; and the total neglect of fertile tracts will, from their accumulated vegetable products, produce peat soils, and bogs. Where successive generations of vegetables have grown upon a soil, Sir H. Davy observes, unless part of their produce has been carried off by man, or consumed by animals, the vegetable matter increases in such a proportion, that the soil approaches to a peat in its nature; and if in a situation where it can receive water from a higher district, it becomes spongy, and permeated with that fluid, and is gradually rendered incapable of supporting the nobler classes of vegetables. Many peat-mosses seem to have been formed by the destruction of forests, in consequence of the improper use of the hatchet by the early cultivators of the country in which they exist: when the trees are felled in the outskirts of a wood, those in the interior are exposed to the influence of the winds; having been accustomed to shelter, they become unhealthy, and die in their new situation; and their leaves and branches gradually decomposing, produce a stratum of vegetable matter. In many of the great bogs in Ireland and Scotland, the larger trees that
are found in the outskirts of them, bear the marks of having been felled. In the interior, few entire trees are found; and the cause is, probably, that they fell by gradual decay; and that the fermentation and decomposition of the vegetable matter was the most rapid where it was in the greatest quantity.

1027. *Spurious peaty soil.* Lakes and pools of water are sometimes filled up by the accumulation of the remains of aquatic plants; and in this case a sort of spurious peat is formed. The fermentation in these cases, however, seems to be of a different kind. Much more gaseous matter is evolved; and the neighbourhood of morasses, in which aquatic vegetables decompose, is usually aguish and unhealthy; whilst that of the true peat, or peat formed on soils originally dry, is always salubrious.

1028. Soils may generally be distinguished from mere masses of earth by their friable texture, dark color, and the presence of some vegetable flour or carbonaceous matter. In uncultivated grounds, soils occupy only a few inches in depth on the surface, unless in crevices, where they had been washed in by rains; and in cultivated soils their depth is generally the same as that to which the implements used in cultivation have penetrated.

1029. Much has been written on soils, and till lately, to very little purpose. All the Roman authors on husbandry treated the subject at length; and in modern times, in this country, copious philosophical discussions on soils were published by Bacon, Evelyn, Bradley and others; but it may be truly said, that in no department of cultivation was ever so much written of so little useful written by practical men. One reason for this failure is, that some of the principal effects of operations on soils are chemical, and chemistry, till within the last forty years, could hardly be considered an inductive science. In so little esteem was it held in Evelyn's time, that he ranks it with astrology, and considers the term as synonymous with alchemy. (Terra, p. 4. and Memoirs, &c.) Jethro Tull, about 60 years after the publication of Evelyn's *Terra,* published a system of culture, in which every thing was referred to mechanical division; but though he referred to this theory the beneficial influence of some excellent practices, yet neither gained ground at the time. The first attempt to treat of soils chemically, was made by Kirwan about 1780, the next by Lord Dundonald in 1795, and then followed Dr. Darwin's *Phytologia* in 1804, and lastly, Sir H. Davy's *Lectures on Agricultural Chemistry* in 1822. It is from the last edition (in-1822) of that valuable work, that we shall chiefly make our selections.

**Sect. II. Classification and Nomenclature of Soils.**

1030. Systematic order and an agreed nomenclature are as necessary in the study of soils as of plants or animals. The number of provincial terms for soils which have found their way into the books on cultivation, is one reason why so little use can be made of their directions.

1031. A correct classification of soils may be founded on the presence or absence of organic and inorganic matter in their basis. This will form two grand classes, viz. primitive soils, or those composed entirely of inorganic matter, and secondary soils, or those composed of organic and inorganic matter in mixtures. These classes may be subdivided into orders founded on the presence or absence of saline, metallic, and carbonic matter. The orders may be subdivided into genera founded on the prevailing earths, salts, metals, or carbon; the genera into species founded on their different mixtures; the species into varieties founded on color, texture; and sub-varieties founded on moisture, dryness, richness, lightness, &c.

1032. In naming the genera of soils, the first thing is to discover the prevailing earth or earths; either the simple earths, as clay, lime, sand, or the particular rocks from which the soil has been produced, as granite, basalt, &c. When one earth prevails, the generic name should be taken from that earth, as clayey soil, calcareous soil, &c.; when two prevail to all appearance equally, then their names must be conjoined in naming the genus, as clay and sand, lime and clay, basalt and sand, &c. The great thing is precision in applying the terms. Thus, as Sir H. Davy has observed, the term sandy soil should never be applied to any soil that does not contain at least seven eights of sand; sandy soils that effervesce with acids should be distinguished by the name of calcareous sandy soil, to distinguish them from those that are siliceous. The term clayey soil should not be applied to any land which contains less than one sixth of impalpable earthy matter, not considerably effervescing with acids; the word loam should be limited to soils, containing at least one third of impalpable earthy matter, copiously effervescing with acids. A soil to be considered as peaty, ought to contain at least one half of vegetable matter. In cases where the earthy part of a soil evidently consists of the decomposed matter of one particular rock, a name derived from the rock may with propriety be applied to it. Thus, if a fine red earth be found immediately above decomposing basalt, it may be denominated basaltic soil. If fragments of quartz and mica be found abundant in the materials of the soil, which is often the case, it may be denominated granite soil; and the same principles may be applied to other like instances. In general, the soils, the materials of which are the most various and heterogeneous, are those called alluvial, or which have been formed from the depositions of rivers; and these deposits may be designated as siliceous, calcareous, or argillaceous; and in some cases the term saline may be added as a specific distinction, applicable, for example, at the embouchure of rivers, where their alluvial remains are overflown by the sea.

1033. In naming the species of soils, greater nicety is required to determine distinctions, than in naming the genera; and there is also some difficulty in applying or devising proper terms. The species are always determined by the mixture of matters, and never by the color or texture of that mixture which belongs to the nomenclature of varieties. Thus a clayey soil with sand is a sandy clay, this is the name of the species; if the mass is yellow, and it is thought worth while to notice that circumstance, then it is a yellow sandy clay, which expresses at once the genus, species, and variety. A soil con-
taining equal parts of clay, lime, and sand, would, as a generic term, be called clay, lime, and sand; if it contained no other mixture in considerable quantity, the term entire, might be added as a specific distinction; and if notice was to be taken of its color or degree of comminution, it might be termed a brown, a fine, a coarse, a stiff, or a free entire clay, lime, and sand.

1034. The following Table enumerates the more common genera, species, and varieties of soils. The application of the terms will be understood by every cultivator, though to attempt to describe the soils either chemically, or empirically (as by sight, smell, or touch), would be a useless waste of time. From a very little experience in the field or garden, more may be gained in the study of soils, than from a volume of such descriptions. This table corresponds with the nomenclature adopted in the agricultural establishments of Fellenberg at Hofwyl in Switzerland, of Professor Thaer at Magelien in Prussia, of Professor Thouin in his lectures at Paris, and in general with that of all the continental professors. It is therefore very desirable that it should become as generally adopted as that of the Linnean system in botany. The principle of the table may be extended so as to include any other soil whatever.
sect. III. Of discovering the Qualities of Soils.

1035. The value of soils to the cultivator, is discoverable botanically, chemically, and mechanically; that is, by the plants that grow on them naturally; by chemical analysis; and by exterior and interior inspection or handling.

Subsect. 1. Of discovering the Qualities of Soils by means of the Plants which grow on them.

1036. Plants are the most certain indicators of the nature of a soil; for while no practical cultivator would engage with land of which he knew only the results of a chemical analysis, or examined by the sight and touch a few bushels which were brought to him, yet every gardener or farmer, who knew the sort of plants it produced, would be at once able to decide as to its value for cultivation.

1037. The leading soils for the cultivator are the clayey, calcareous, sandy, ferruginous, peaty, saline, moist or aquatic, and dry. The following are the plants by which such soils are distinguished in most parts of Europe: —

Argillaceous. Tussilago farfara, Potentilla anserina, argentea, and reptans. Thalictrum flavum, Carex, many species. Juncus, various species. Orotus tuberosus, Lotus major, and cornicolatus. Saponaria officinalis. But the Tussilago farfara is a certain and universal sign of an argillaceous soil, and is the chief plant found on the alum grounds of Britain, France, and Italy.

Ferruginous. Rumex acetosa, and acetosella.

Very dry. Arenaria rubra, Rumex acetosella, Thymus Scoppyllum, Acinos vulgaris, Trifolium arvense.

1038. These plants are not absolutely to be depended on, however, even in Britain; and in other countries they are sometimes found in soils directly opposite. Still, the saintfoin is almost always an indication of a calcareous soil; the common coltsfoot (Tussilago farfara), of blue clay; the arenaria rubra, of poor sand; the small wood-sorrel of the presence of iron. The aquatic, peaty, and saline soils are almost every where indicated by their appropriate plants; a proof, as we have before stated, that the climate and natural irrigation of plants have much more influence on their habits than mere soil. (See the Stationes Plantarum of Lin. and the Flora Francaise of De Candolle; Galpin’s Compendium Fl. Brit.; Smith’s Flora Brit.; Kent’s Hints; and Farmers’ Mag. Feb. 1819.)

Subsect. 2. Of discovering the Qualities of Soils by chemical Analysis.

1039. Chemical analysis is much too nice an operation for general purposes. It is not likely that many practical cultivators will ever be able to conduct the analytic process with sufficient accuracy, to enable them to depend on the result. But still such a knowledge of chemistry as shall enable the cultivator to understand the nature of the process and its results, when made and presented to him by others, is calculated to be highly useful, and ought to be acquired by every man whose object is to join theoretical to practical knowledge. If it so happens that he can perform the operations of analysis himself, so much the better, as far as that point is concerned; but on the whole, such knowledge and adroitness is not to be expected from men who have so many other points demanding their attention, and who will, therefore, effect their purpose much better by collecting proper specimens of the soils to be studied, and sending them for analysis to a respectable operative chemist.

1040. In selecting specimens, where the general nature of the soil of a field is to be
ascertained, portions of it should be taken from different places, two or three inches below the surface, and examined as to the similarity of their properties. It sometimes happens, that upon plains, the whole of the upper stratum of the land is of the same kind, and in this case, one analysis will be sufficient; but in valleys, and near the beds of rivers, there are very great differences, and it now and then occurs that one part of a field is calcareous, and another part siliceous; and in this case, and in analogous cases, the portions different from each other should be separately submitted to experiment. Soils, when collected, if they cannot be immediately examined, should be preserved in phials quite filled with them, and closed with ground glass stoppers. The quantity of soil most convenient for a perfect analysis is from two to four hundred grains. It should be collected in dry weather, and exposed to the atmosphere till it becomes dry to the touch.

1041. The soil best suited for culture, according to the analysis of Bergman, contains four parts of clay, three of sand, two of calcareous earth, and one of magnesia: and, according to the analysis of Fourcroy and Hassenfratz, 9216 parts of fertile soil contained 305 parts of carbon, together with 279 parts of oil; of which, according to the calculations of Lavoisier, 220 parts may be regarded as carbon: so that the whole of the carbon contained in the soil in question may be estimated at about 525 parts, exclusive of the roots of vegetables, or to about one sixteenth of its weight. Young observed that equal weights of different soils, when dried and reduced to powder, yielded by distillation quantities of air somewhat corresponding to the ratio of their values. The air was a mixture of fixed and inflammable airs, proceeding probably from decomposition of the water; but, partly, it may be presumed, from its capacity of abstracting a portion of air from the atmosphere, which the soil at least is capable of doing. The following is the analysis of a fertile soil, as occurring in the neighbourhood of Bristol: — In 400 grains, there were of water, 52; siliceous sand, 240; vegetable fibre, 5; vegetable extract, 3; alumine, 48; magnesia, 2; oxide of iron, 14; calcareous earth, 30; loss, 6. But Kirwan has shown in his Geological Essays, that the fertility of a soil depends in a great measure upon its capacity for retaining water: and if so, soils containing the same ingredients must be also equally fertile, all other circumstances being the same; though it is plain that their actual fertility will depend ultimately upon the quantity of rain that falls, because the quantity suited to a wet soil cannot be the same that is suited to a dry soil. And hence it often happens that the ingredients of the soil do not correspond to the character of the climate. Silica exists in the soil under the modification of sand, and alumine under the modification of clay. But the one or the other is often to be met with in excess or defect. Soils in which the sand preponderates retain the least moisture; and soils in which the clay preponderates retain the most: the former are dry soils, the latter are wet soils. But it may happen that neither of them is sufficiently favorable to culture; in which case, their peculiar defect or excess must be supplied or retrenched before they can be brought to a state of fertility.

1042. Use of the result of analysis. In the present state of chemical science, Dr. Ure observes, no certain system can be devised for the improvement of lands, independently of experiment; but there are few cases in which the labor of analytical trials will not be amply repaid by the certainty with which they denote the best methods of melioration; and this will particularly happen, when the defect of composition is found in the proportions of the primitive earth. In supplying organic matter, a temporary food only is provided for plants, which is in all cases exhausted by means of a certain number of crops: but when a soil is rendered of the best possible constitution and texture, with regard to its earthly parts, its fertility may be considered as permanently established. It becomes capable of attracting a very large portion of vegetable nourishment from the atmosphere, and of producing its crops with comparatively little labor and expense. (Dict. of Chem. art. Soils.)

Subsect. 3. Of discovering the Qualities of a Soil mechanically and empirically.

1043. The physical properties of soils, and some of their most important constituents relatively to the cultivator, may be ascertained to a certain extent by various and very simple means.

1044. The specific gravity of a soil, or the relation of its weight to that of water, may be ascertained by introducing into a phial, which will contain a known quantity of water, equal volumes of water and of soil, and this may be easily done by pouring in water till it is half full, and then adding the soil till the fluid rises to the mouth; the difference between the weight of the soil and that of the water, will give the result. Thus if the bottle contains four hundred grains of water, and gains two hundred grains when half filled with water and half with soil, the specific gravity of the soil will be 2, that is, it will be twice as heavy as water, and if it gained one hundred and sixty-five grains, its specific gravity would be 1825, water being 1000.
1045. The presence of clay and sand in any soil is known, the first by its tenacity, the other by its roughness to the touch, and by scratching glass when rubbed on it.

1046. The presence of calcareous matter in soil may be ascertained by simply pouring any acid on it, and observing if it effervesces freely. Calcareous soils are also softer to the touch than any other.

1047. The presence of organised matter in any soil may be ascertained very satisfactorily by weighing it after being thoroughly dried; then subjecting it to a red heat, and weighing it again, the weight last found will be the proportion of organic matter. The same object may also be attained by ascertaining the specific gravity of the soil, but with less accuracy.

1048. The presence of metallic oxides in a soil may generally be known by their color. Ferruginous soils, are red or yellow; cupreous soils, interspersed with greenish streaks, &c.

1049. The presence of salts, sulphur, coal, &c. may be known by the absence or peculiarity of vegetation, as well as by color, and the appearance of the water of such soils.

1050. The capacity of a soil for retaining water may be thus ascertained. An equal portion of two soils, perfectly dry, may be introduced into two tall glass cylindrical vessels, (fig. 74.) in the middle of each of which a glass tube is previously placed. The soils should be put into each in the same manner, not compressed very hard, but so as to receive a solidity approaching to that which they possessed when first obtained for trial. If, after this preparation, a quantity of water be poured into the glass tubes, it will subside; and the capillary attraction of the soils will conduct it up the cylinders towards the tops of the vessels. That which conducts it most rapidly, provided it does not rise from the weight of the incumbent column of water in the tube, may be pronounced to be the better soil. (Grisenthwaite.)

Sect. IV. Of the Uses of the Soil to Vegetables.

1051. Soils afford to plants a fixed abode and medium of nourishment. Earths, exclusively of organised matter and water, are allowed by most physiologists, to be of no other use to plants than that of supporting them, or furnishing a medium by which they may fix themselves to the globe. But earths and organic matter, that is, soils, afford at once support and food.

1052. The pure earths merely act as mechanical and indirect chemical agents in the soil. The earths consist of metals united to oxygen, and these metals have not been decomposed; there is consequently no reason to suppose that the earths are convertible into the elements of organised compounds, that is, into carbon, hydrogen, and azote. Plants have been made to grow in given quantities of earth. They consume very small portions only; and what is lost may be accounted for by the quantities found in their ashes; that is to say, it has not been converted into any new products. The carbonic acid united to lime or magnesia, if any stronger acid happens to be formed in the soil during the fermentation of vegetable matter, which will disengage it from the earths, may be decomposed; but the earths themselves cannot be supposed convertible into other substances, by any process taking place in the soil. In all cases the ashes of plants contain some of the earths of the soil in which they grow; but these earths, as has been ascertained from the ashes afforded by different plants, never equal more than one fiftieth of the weight of the plant consumed. If they be considered as necessary to the vegetable, it is as giving hardness and firmness to its organisation. Thus, it has been mentioned that wheat, oats, and many of the hollow-stalked grasses, have an epidermis principally of siliceous earth; the use of which seems to be to strengthen them, and defend them from the attacks of insects and parasitical plants.

1053. The true nourishment of plants is water, and decomposing organic matter; both these exist only in soils, not in pure earths; but the earthy parts of the soils are useful in retaining water, so as to supply it in the proper proportions to the roots of the vegetables, and they are likewise efficacious in producing the proper distribution of the animal or vegetable matter. When equally mixed with it they prevent it from decomposing too rapidly; and by their means the soluble parts are supplied in proper proportions.

1054. The soil is necessary to the existence of plants, both as affording them nourishment, and enabling them to fix themselves in such a manner as to obey those laws by which their radicles are kept below the surface, and their leaves exposed to the free atmosphere. As the systems of roots, branches, and leaves, are very different in different vegetables, so they flourish most in different soils; the plants that have bulbous roots require a looser and a lighter soil than such as have fibrous roots; and the plants possessing only short
fibrous radicles demand a firmer soil than such as have tap-roots or extensive lateral roots.

1055. The constituent parts of the soil which give tenacity and coherence are the finely divided matters; and they possess the power of giving those qualities in the highest degree when they contain much alumina. A small quantity of finely divided matter is sufficient to fix a soil for the production of turnips and barley; and a tolerable crop of turnips has been produced on a soil containing 11 parts out of 12 sand. A much greater proportion of sand, however, always produces absolute sterility. The soil of Bagshot heath, which is entirely devoid of vegetable covering, contains less than one twentieth of finely divided matter: 400 parts of it, which had been heated red, afforded 380 parts of coarse siliceous sand; 9 parts of fine siliceous sand, and 11 parts of impalpable matter, which was a mixture of ferruginous clay with carbonate of lime. Vegetable or animal matters, when finely divided, not only give coherence, but likewise softness and penetrability; but neither they nor any other part of the soil must be in too great proportion; and a soil is unproductive if it consist entirely of impalpable matters. Pure alumina or silica, pure carbonate of lime, or carbonate of magnesia, are incapable of supporting healthy vegetation; and no soil is fertile that contains as much as 19 parts out of 20 of any of these constituents.

1056. A certain degree of friability or looseness of texture is also required in soils, in order that the operations of culture may be easily conducted; that moisture may have free access to the fibres of the roots, that heat may be readily conveyed to them, and that evaporation may proceed without obstruction. These are commonly attained by the presence of sand. As alumina possesses all the properties of adhesiveness in an eminent degree, and is the source of friability, it is obvious that a mixture of those two earths, in suitable proportions, would furnish every thing wanted to form the most perfect soil as to water and the operations of culture. In a soil so compounded, water will be presented to the roots by capillary attraction. It will be suspended in it, in the same manner as it is suspended in a sponge, not in a state of aggregation, but minute division, so that every part may be said to be moist, but not wet. (Grisenthvative.)

1057. The water chemically combined amongst the elements of soils, unless in the case of the decomposition of animal or vegetable substances, cannot be absorbed by the roots of plants; but that adhering to the parts of the soil is in constant use in vegetation. Indeed there are few mixtures of the earths found in soils that contain any chemically combined water; water is expelled from the earth by most substances that combine with them. Thus, if a combination of lime and water be exposed to carbonic acid, the carbonic acid takes the place of water; and compounds of alumina and silica, or other compounds of the earths, do not chemically unite with water; and soils, as it has been stated, are formed either by earthly carbonates, or compounds of the pure earths and metallic oxides. When saline substances exist in soils, they may be united to water both chemically and mechanically; but they are always in too small a quantity to influence materially the relations of the soil to water.

1058. The power of the soil to absorb water by cohesive attraction depends in great measure upon the state of division of its parts; the more divided they are, the greater is their absorbent power. The different constituent parts of soils likewise appear to act, even by cohesive attraction, with different degrees of energy. Thus vegetable substances appear to be more absorbent than animal substances; animal substances more so than compounds of alumina and silica; and compounds of alumina and silica more absorbent than carbonates of lime and magnesia: these differences may, however, possibly depend upon the differences in their state of division, and upon the surface exposed.

1059. The power of soils to absorb water from air is much connected with fertility. When this power is great, the plant is supplied with moisture in dry seasons; and the effect of evaporation in the day is counteracted by the absorption of aqueous vapor from the atmosphere, by the interior parts of the soil during the day, and by both the exterior and interior during the night. The stiff clays approaching to pipe-clays in their nature, which take up the greatest quantity of water when it is poured upon them in a fluid form, are not the soils which absorb most moisture from the atmospheric in dry weather. They cake, and present only a small surface to the air; and the vegetation on them is generally burnt up almost as readily as on sands. The soils that are most efficient in supplying the plant with water by atmospheric absorption, are those in which there is a due mixture of sand, finely divided clay, and carbonate of lime, with some animal or vegetable matter, and which are so loose and light as to be freely permeable to the atmosphere. With respect to this quality, carbonate of lime, and animal and vegetable matter, are of great use in soils; they give absorbent power to the soil without giving it likewise tenacity; sand, which also destroys tenacity, on the contrary, gives little absorbent power. The absorbent powers of soils, with respect to atmospheric moisture, is always greatest in the most fertile soils; so that it affords one method of judging of the productiveness of land.
1060. As examples of the absorbent powers of soils: 1000 parts of a celebrated soil from Ormistoun, in East Lothian, which contained more than half its weight of finely divided matter, of which 11 parts were carbonate of lime, and 9 parts vegetable matter, when dried at 212°, gained in an hour by exposure to air saturated with moisture, at a temperature of 62°, 18 grains. 1000 parts of a very fertile soil from the banks of the river Parret, in Somersetshire, under the same circumstances, gained 16 grains. 1000 parts of a soil from Mersea, in Essex, gained 13 grains. 1000 grains of a fine sand, from Essex, gained 11 grains. 1000 of a coarse sand gained only 8 grains. 1000 of a soil of Bagshot heath gained only 3 grains.

1061. The absorbent powers of soils ought to vary with the climate in which they are situated. The absorption of moisture ought to be much greater in warm or dry countries, than in cold and moist ones; and the quantity of clay, or vegetable, or animal matter in soils greater. Soils also on declivities ought to be more absorbent than in plains or in the bottom of valleys. Their productiveness likewise is influenced by the nature of the subsoil, or the stratum on which they rest. When soils are immediately situated upon a bed of rock or stone, they are much sooner rendered dry by evaporation than where the sub-soil is of clay or marl; and a prime cause of the great fertility of the land in the moist climate of Ireland, is the proximity of the rocky strata to the soil. A clayey sub-soil will sometimes be of material advantage to a sandy soil; and in this case it will retain moisture in such a manner as to be capable of supplying that lost by the earth above, in consequence of evaporation or the consumption of it by plants. A sandy or gravelly sub-soil often corrects the imperfections of too great a degree of absorbent power in the true soil. In calcareous countries, where the surface is a species of marl, the soil is often found only a few inches above the limestone; and its fertility is not impaired by the proximity of the rock; though in a less absorbent soil, this situation would occasion barrenness; and the sandstone and limestone-hills in Derbyshire and North Wales, may be easily distinguished at a distance, in summer, by the different tints of the vegetation. The grass on the sandstone-hills usually appears brown and burnt up; that on the limestone-hills flourishing and green.

1062. In a moist climate, where the quantity of rain that falls annually equals from 40 to 60 inches, as in Lancashire, Cornwall, and some parts of Ireland, a siliceous sandy soil is much more productive than in dry districts; and in such situations wheat and beans will require a less coherent and absorbent soil than in drier situations; and plants having bulbous roots will flourish in a soil containing as much as 14 parts out of 15 of sand. Even the exhausting powers of crops will be influenced by like circumstances. In cases where plants cannot absorb sufficient moisture, they must take up more manure. And in Ireland, Cornwall, and the western Highlands of Scotland, corn will exhaust less than in dry inland situations. Oats, particularly in dry climates, are impoverishing in a much higher degree than in moist ones.

1063. Many soils are popularly distinguished as cold or hot; and the distinction, though at first view it may appear to be founded on prejudice, is really just. Some soils are much more heated by the rays of the sun, all other circumstances being equal, than others; and soils brought to the same degree of heat, cool in different times, I. e. some cool much faster than others. This property has been very little attended to in a philosophical point of view; yet it is of the highest importance in culture. In general, soils that consist principally of a stiff white clay are diffusely heated; and being usually very moist, they retain their heat only for a short time. Chalks are similar in one respect, that they are diffusely heated; but being drier they retain their heat longer, less being consumed in causing the evaporation of their moisture. A black soil, containing much soft vegetable matter, is most heated by the sun and air; and the colored soils, and the soils containing much carbonaceous matter, or ferruginous matter, exposed under equal circumstances to sun, acquire a much higher temperature than pale-colored soils.

1064. When soils are perfectly dry, those that most readily become heated by the solar rays, likewise cool most rapidly; but in dark-colored soil, (that which contains abundance of animal or vegetable matter; substances which most facilitate the diminution of temperature,) when heated to the same degree, provided it be within the common limits of the effect of solar heat, will cool more slowly than a wet, pale soil, entirely composed of earthy matter. Sir H. Davy "found that a rich black mould, which contained nearly one fourth of vegetable matter, had its temperature increased in an hour from 65° to 86° by exposure to sunshine; whilst a chalk soil was heated only to 69° under the same circumstances. But the mould removed into the shade, where the temperature was 62°, lost, in half an hour, 15°; whereas the chalk, under the same circumstances, had lost only 4°. A brown fertile soil and a cold barren clay were each artificially heated to 88°, having been previously dried; they were then exposed in a temperature of 57°; in half an hour the dark soil was found to have lost 9° of heat; the clay had lost only 6°. An equal portion of the clay containing moisture, after being heated to 88°, was exposed in a temperature of 53°; in less than a quarter of an hour it was found to have gained the
temperature of the room. The soils in all these experiments were placed in small tin-plate trays two inches square, and half an inch in depth; and the temperature ascertained by a delicate thermometer. Thus the temperature of the surface, when bare and exposed to the rays of the sun, affords at least one indication of the degrees of its fertility; and the thermometer may be sometimes a useful instrument to the purchaser or improver of lands."

1065. _The moisture in the soil and sub-soil materially affects its temperature, and prevents, as in the case of constantly saturated aquatic soils, their ever attaining to any great degree either of heat or cold. The same observation will apply to moist peaty soils, or peat-bogs._

1066. _Chemical agency of soils._ Besides these uses of soils, which may be considered mechanical, there is, Sir H. Davy observes, another agency between soils and organisable matters, which may be regarded as chemical in its nature. The earths, and even the earthy carbonates, have a certain degree of chemical attraction for many of the principles of vegetable and animal substances. This is easily exemplified in the instance of alumina and oil; if an acid solution of alumina be mixed with a solution of soap, which consists of oily matter and potassa, the oil and the alumina will unite and form a white powder, which will sink to the bottom of the fluid. The extract from decomposing vegetable matter, when boiled with pipe-clay or chalk, forms a combination by which the vegetable matter is rendered more difficult of decomposition and of solution. Pure silica and siliceous sands have little action of this kind; and the soils which contain the most alumina and carbonate of lime, are those which act with the greatest chemical energy in preserving manures. Such soils merit the appellation, which is commonly given to them, of rich soils; for the vegetable nourishment is long preserved in them, unless taken up by the organs of plants. Siliceous sands, on the contrary, deserve the term hungry, which is commonly applied to them; for the vegetable and animal matters they contain, not being attracted by the earthy constituent parts of the soil, are more liable to be decomposed by the action of the atmosphere, or carried off from them by water. In most of the black and brown rich vegetable moulds, the earths seem to be in combination with a peculiar extractive matter, afforded during the decomposition of vegetables; this is slowly taken up or attracted from the earths by water, and appears to constitute a prime cause of the fertility of the soil.

1067. _Thus all soils are useful to plants, as affording them a fixed abode and a range for their roots to spread in search of food; but some are much more so than others, as better adapted by their constituent parts, climate, inclination of surface and subsoil attracting and supplying food._

_Sect. V._ Of the Improvement of Soils.

1068. _Soils may be rendered more fit for answering the purposes of vegetation by pulverisation, by consolidation, by exposure to the atmosphere, by an alteration of their constituent parts, by changing their condition in respect to water, by changing their position in respect to atmospheric influence, and by a change in the kinds of plants cultivated. All these improvements are independently of the application of manures._

_Subsect. I._ Pulverisation.

1069. _The mechanical division of the parts of soils is a very obvious improvement, and applicable to all in proportion to their adhesive texture. Even a free siliceous soil will, if left untouched, become too compact for the proper admission of air, rain, and heat, and for the free growth of the fibres; and strong upland clays, not submitted to the plough or the spade, will, in a few years, be found in the possession of fibrous-rooted perennial grasses, which form a clothing on their surface, or strong tap-rooted trees, as the oak, which force their way through the interior of the mass. Annuals and ramentaceous-rooted herbaceous plants cannot penetrate into such soils._

1070. _The first object of pulverisation is to give scope to the roots of vegetables, for without abundance of roots no plant will become vigorous, whatever may be the richness of the soil in which it is placed. The fibres of the roots, as we have seen (740.), take up the extract of the soil by intro-susception; the quantity taken up, therefore, will not depend alone on the quantity in the soil, but on the number of absorbing fibres. The more the soil is pulverised, the more these fibres are increased, the more extract is absorbed, and the more vigorous does the plant become. Pulverisation, therefore, is not only advantageous previous to planting or sowing, but also during the progress of vegetation, when applied in the intervals between the plants. In this last case it operates also in the way of pruning, and by cutting off or shortening the extending fibres, causes them to branch out numerous others, by which the mouths or pores of the plants are greatly increased, and such food as is in the soil has the better chance of being sought after, and taken up by them._ Tull and Du Hamel relate various experiments which decidedly prove that, _ceteris paribus_, the multiplication of the fibres is as the inter-pulverisation;
but the strength of the vegetable, in consequence of this multiplication of fibres, must depend a good deal on the quantity of food or of extract within their reach. The root of a willow-tree, as we have seen (782.), has the fibres prodigiously increased by coming in contact with the water in a river, and so have various other aquatic trees and plants, as alder, mint, lysimachia thyrsiflora, calla palustris, cenanthe fastulosa, &c.; but their herbs or trunks are not proportionally increased unless the water be impregnated with organised remains.

1071. Pulverisation increases the capillary attraction, or sponge-like property of soils, by which their humidity is rendered more uniform. It is evident this capillary attraction must be greatest where the particles of the earth are finely divided; for gravels and sands hardly retain water at all, while clays, not opened by pulverisation or other means, either do not absorb water, or when, by long action it is absorbed, they retain too much. Water is not only necessary to the growth of plants as such, but it is essential to the production of extract from the vegetable matters which they contain; and unless the soil, by pulverisation or otherwise, is so constituted as to retain the quantity of water requisite to produce this extract, the addition of manures will be in vain. Manure is useless to vegetation till it becomes soluble in water, and it would remain useless in a state of solution, if it so abounded as wholly to exclude air, for then the fibres or mouths, unable to perform their functions, would soon decay and rot off.

1072. The temperature of a soil is greatly promoted by pulverisation. Earths, Grisenthwaite observes, are also amongst the worst conductors of heat with which we are acquainted, and consequently, it would be a considerable time before the gradually increasing temperature of spring could communicate its genial warmth to the roots of vegetables, if their lower strata were not heated by some other means. To remove this defect, which always belongs to a close compact soil, it is necessary to have the land open, that there may be a free ingress of the warm air and tepid rains of spring.

1073. Pulverisation contributes to the increase of vegetable food. Water is known to be a condenser and solvent of carbonic acid gas, which, when the land is open, can be immediately carried to the roots of vegetables, and contribute to their growth; but if the land be close, and the water lie on or near its surface, then the carbonic acid gas, which always exists in the atmosphere and is carried down by rains, will soon be dissipated. An open soil is also almost suitable for effecting those changes in the manure itself, which are equally necessary to the preparation of such food. Animal and vegetable substances, exposed to the alternate action of heat, moisture, light, and air, undergo spontaneous decompositions, which would not otherwise take place.

1074. By means of pulverisation a portion of atmospheric air is buried in the soil. This air, so confined, is decomposed by the moisture retained in the earthy matters. Ammonia is formed by the union of the hydrogen of the water with the nitrogen of the atmosphere; and nitre, by the union of oxygen and nitrogen; the oxygen may also unite with the carbon contained in the soil, and form carbonic acid gas, and carburetted hydrogen. Heat is given out during these processes, and "hence," as Dr. Darwin remarks (Phytologia, sect. xii. 1.), "the great propriety of cropping lands immediately after they had been comminated and turned over; and this the more especially, if manure has been added at the same time, as the process of fermentation will go on faster when the soil is loose, and the interstices filled with air, than afterwards, when it becomes compressed with its own gravity, the relaxing influence of rains, and the repletion of the partial vacuums formed by the decomposition of the enclosed air. The advantage of the heat thus obtained in exciting vegetation, whether in a seed or root, especially in spring, when the soil is cold, must be very considerable."

1075. The great advantages of pulverisation deceived Tell, who fancied that no other assistances were required in the well-management of the business of husbandry. A knowledge of chemistry, in its present improved state, would have enabled him to discover that the pulverisation of the soil was of no other benefit to the plants that grow in it than as it "increased the number of their fibrous roots or mouths by which they imbibe their food, facilitated the more speedy and perfect preparation of this food, and conducted the food so prepared more regularly to their roots." Of this food itself it did not produce one particle.

1076. The depth of pulverisation, Sir H. Davy observes, "must depend upon the nature of the soil, and of the sub-soil. In rich clayey soils it can scarcely be too deep; and even in sands, unless the sub-soil contains some principles noxious to vegetables, deep commination should be practised. When the roots are deep, they are less liable to be injured either by excess of rain or drought; the radicles are shot forth into every part of the soil; and the space from which the nourishment is derived is more considerable than when the seed is superficially inserted in the soil."

1077. Pulverisation should, in all cases, be accompanied with the admixture of the partes of soils by turning them over. It is difficult, indeed, to pulverise without effecting this
end, at least by the implements in common use; but if it could be effected, it would be injurious, because the difference of gravity between the organised matters and the earths, has a constant tendency to separate them, and stirring a soil only by forks or pronged implements, such as cultivators, would, in a short time, leave the surface of the soil too light and spongy, and the lower part too compact and earthy.

**SUBJET. 2. Of the Improvement of Soils by Compression.**

1078. *Mechanical consolidation* will improve some soils, such as spongy peats and light dusty sands. It is but a limited source of improvement, but still it deserves to be noticed.

1079. *The proper degree of adhesiveness* is best given to loose soils by the addition of earthy matters; but mere rolling and treading are not to be altogether rejected. To be benefited by rolling a soil must be dry, and the operation must not be carried too far. A peat-bog drained and rolled, will sooner become covered with grasses than one equally well drained and left alone. Drifting sands may be well rolled when wet, and by repeating the process after rains they will in time acquire a surface of grass or herbage. Every agriculturist knows the advantages of rolling light soils after sowing, or even treading them with sheep. Gardeners also tread in seeds on certain soils.

**SUBJET. 3. Of the Improvement of Soils by Aeration or Fallowing.**

1080. *Soils are benefited by the free admission of the weather to their interior parts.* This is generally considered as one of the advantages of fallowing, and its use in gardening is experienced in compost heaps, and in winter and summer ridging. The precise advantages, however, of exposure to the air, independently of the concurrent influence of water, heat, and the other effects mentioned as attendant on pulverisation, do not seem at present to be correctly ascertained. It is allowed that carbonic acid gas may be absorbed by calcareous earths, and Dr. Thomson considers that the earths alone may thus probably administer food to plants; but Sir H. Davy seems to consider mere exposure to the atmosphere as of no benefit to soils whatever. "It has been supposed by some writers," he says, "that certain principles necessary to fertility are derived from the atmosphere, which are exhausted by a succession of crops, and that these are again supplied during the repose of the land, and the exposure of the pulverised soil to the influence of the air; but this in truth is not the case. The earths commonly found in soils cannot be combined with more oxygen; none of them unite to azote; and such of them as are capable of attracting carbonic acid, are always saturated with it in those soils on which the practice of fallowing is adopted."

1081. *Aeration and repose, or summer fallow.* "The vague ancient opinion of the use of nitre, and of nitrous salts in vegetation," Sir H. Davy says, "seems to have been one of the principal speculative reasons for the defence of summer fallows. Nitrous salts are produced during the exposure of soils containing vegetable and animal remains, and in greatest abundance in hot weather; but it is probably by the combination of azote from these remains with oxygen in the atmosphere that the acid is formed; and at the expense of an element, which otherwise would have formed ammonia; the compounds of which are much more efficacious than the nitrous compounds in assisting vegetation." It is proper to observe that this reasoning is more speculative than experimental, and seems influenced, in some degree, by the opinion adopted by the author, that fallows are of little use in husbandry. One obvious advantage of aeration in summer, or a summer fallow, is, that the soil may thus be heated by the sun to a degree which it never could be, if partially covered with the foliage of even the widest-drilled crops. For this purpose, if the soil is laid up in large lumps, it is evident it will receive more heat by exposing a greater surface to the atmosphere, and it will retain this heat longer than can be expected, from the circumstance of the lumps reflecting back the rays of heat radiated by each other. A clayey soil, in this way, it is said (Farmers' Magazine, 1815), may be heated to 120°, which may in some degree alter its absorbent powers as to water, and contribute materially to the destruction of vegetable fibre, insects, and their eggs. By the aeration of lands in winter, minute mechanical division is obtained by the freezing of the water in the soil; for, as water in the solid state occupies more space than when fluid, the particles of earthy matters and of decomposing stones are thus rent asunder, and crumble down in a fine mould. Rough stony soils will thus receive an accession to their finer soil every winter.

1082. *Agricultural experience* has fully proved that fallows are the only means by which stiff clays in moist climates can be effectually cleared of weeds. Supposing therefore that no other advantage whatever was obtained, that no nutritive matter was imbied from the atmosphere, and the soil was neither chemically nor mechanically benefited by aeration, this benefit alone—the effectual eradication of weeds—is sufficient to justify the use of fallows on such soils.
SUBSECTION 4. Alteration of the constituent Parts of Soils.

1083. The constituent parts of soils may be altered by the addition or subtraction of ingredients in which they are deficient, or superabound, and by the chemical changes of some constituent part or parts by the action of fire.

1084. In ascertaining the composition of faulty soils with a view to their improvement by adding to their constituent parts, any particular ingredient which is the cause of their unproductiveness, should be particularly attended to; if possible, they should be compared with fertile soils in the same neighbourhood, and in similar situations, as the difference of the composition may, in many cases, indicate the most proper methods of improvement.

If, on washing a sterile soil, it is found to contain the salts of iron, or any acid matter, it may be ameliorated by the application of quick-lime. A soil of good apparent texture, containing sulphate of iron, will be sterile; but the obvious remedy is a top-dressing with lime, which converts the sulphate into manure. If there be an excess of calcareous matter in the soil, it may be improved by the application of sand or clay. Soils too abundant in sand are benefited by the use of clay, or marl, or vegetable matter. Light sands are often benefited by a dressing of peat, and peats by a dressing of sand; though the former is in its nature but a temporary improvement. When peats are acid, or contain ferruginous salts, calcareous matter is absolutely necessary in bringing them into cultivation. The best natural soils are those of which the materials have been derived from different strata, which have been minutely divided by air and water, and are intimately blended together; and in improving soils artificially, the cultivator cannot do better than imitate the processes of nature. The materials necessary for the purpose are seldom far distant; coarse sand is often found immediately on chalk, and beds of sand and gravel are common below clay. The labor of improving the texture or constitution of the soil, is repaid by a great permanent advantage, — less manure is required, and its fertility insured; and capital laid out in this way secures for ever the productiveness, and consequently the value of the land.

1085. The removal of superabundant ingredients in soils may sometimes be one of the simplest and most effectual means of their improvement. It occasionally happens that the surface of a well proportioned soil is thickly covered with peat, with drifted sand, with gravel, or with small stones. Extensive examples of the former occur in Stirlingshire, and of the latter in Norfolk. In such cases, a simple and effectual mode of improvement consists in removing the superincumbent strata, and cultivating that below. This can seldom be put in practice on a large scale, with such heavy materials as gravel or stones; but some hundreds of acres of rich alluvial soil, deeply covered by peat, have been harel and cultivated in Flanders moss in Stirlingshire; an operation commenced by the celebrated Lord Kaimes, (Gen. Rep. of Scot. App. v. 5.) copied by his neighbours, and continued by his and their successors. The moss is floated off by streams of water, which empty themselves in the Frith of Forth. In this river, by the winds and tides, it is cast on shore in the bays and recesses, impregnated with salt; and here it engenders vegetation on the encroaching surfaces of sand and gravel. Coatings of sand or gravel can seldom be removed on a scale of sufficient extent for agriculture, but have, in some instances, for the purposes of gardening. Sometimes this improvement may be effected by trenching down the surface, and raising up a stratum of better earth.

1086. Incineration. The chemical changes which can be effected in soils by incineration are considerable. This practice was known to the Romans, is more or less in use in most parts of Europe, is mentioned as an approved practice by our oldest agricultural writers, and has lately excited some degree of attention from the successful experiments of different cultivators. (Farmer's Magazine, 1810 to 1815, and Farmers' Journal, 1814 to 1821.)

1087. The theory of burning soils is thus given by Sir H. Davy. It rests, he says, entirely on chemical doctrines. The bases of all common soils, are mixtures of the primitive earths and oxide of iron; and these earths have a certain degree of attraction for each other. To regard this attraction in its proper point of view, it is only necessary to consider the composition of any common siliceous stone. Feldspar, for instance, contains siliceous, aluminous, calcareous earths, fixed alkali, and oxide of iron, which exist in one compound, in consequence of their chemical attractions for each other. Let this stone be ground into impalpable powder, it then becomes a substance like clay, if the powder be heated very strongly, it fuses, and on cooling forms a coherent mass similar to the original stone; the parts separated by mechanical division adhere again in consequence of chemical attraction. If the powder is heated less strongly, the particles only superficially combine with each other, and form a gritty mass, which, when broken into pieces, has the characters of sand. If the power of the powdered feldspar to absorb water from the atmosphere before, and after the application of the heat, be compared, it is found much less in the last case. The same effect takes place when the powder of other siliceous or aluminous
1088. The advantages of burning are that it renders the soil less compact, less tenacious and retentive of moisture; and when properly applied, may convert a matter that was stiff, damp, and in consequence cold, into one powdery, dry, and warm, and much more proper as a bed for vegetable life.

1089. The great objection made by speculative chemists to paring and burning, is, that it destroys vegetable and animal matter, or the manure in the soil; but in cases in which the texture of its earthy ingredients is permanently improved, there is more than a compensation for this temporary disadvantage. And in some soils where there is an excess of inert vegetable matter, the destruction of it must be beneficial; and the carbonaceous matter remaining in the ashes may be more useful to the crop than the vegetable fibre from which it was produced.

1090. Three specimens of ashes from different lands that had undergone paring and burning were examined by chemical analysis. The first was from a chalk soil, and 200 grains contained 80 of carbonate of lime, 11 gypsum, 9 charcoal, 15 oxide of iron, 3 saline matter, sulphate of potash, muriate of magnesia, with a minute quantity of vegetable alkali. The remainder alumina and silica. Suppose 2660 bushels to be the common produce of an acre of ground, then, according to this calculation, they would give 172,900 lbs., containing carbonate of lime 691,600 lbs., gypsum 9509•5., oxide of iron 12,967•5., saline matter 2593•5., charcoal 7780•5. In this instance there was undoubtedly a very considerable quantity of matter capable of being active as manure produced in the operation of burning. The charcoal very finely divided, and exposed on a large surface, must be gradually converted into carboonic acid. And gypsum and oxide of iron seem to produce the very best effects when applied to lands containing an excess of carbonate of lime. The second specimen was from a soil near Coleorton, in Leicestershire, containing only four per cent. of carbonate of lime, and consisting of three fourths light siliceous sand, and about one fourth clay. This had been turf before burning, and 100 parts of the ashes gave 6 parts charcoal, 3 muriate of soda and sulphate of potash, with a trace of vegetable alkali, 9 oxide of iron, and the remainder the earths. In this instance, as in the other, finely divided charcoal was found, the solubility of which would be increased by the presence of the alkali. The third instance was that of a stiff clay, from Mount's Bay, Cornwall. This land has been brought into cultivation from a heath, by burning, about ten years before; but having been neglected, furze was springing up in different parts of it, which gave rise to the second paring and burning. 100 parts of the ashes contained 8 parts of charcoal, 2 of saline matter, principally common salt, with a little vegetable alkali, 7 oxide of iron, 2 carbonate of lime, the remainder alumina and silica. Here the quantity of charcoal was greater than in the other instances. The salt was probably owing to the vicinity of the sea, it being but two miles off. In this land there was certainly an excess of dead vegetable fibre, as well as unprofitable living matter.

1091. Causes of the effects of burning soil. Many obscure causes have been referred to for the purpose of explaining the effects of paring and burning; but they may be referred entirely to the diminution of the coherence and tenacity of clays, and to the destruction of inert and useless vegetable matter, and its conversion into a manure. Dr. Darwin, in his Phytologia, has supposed that clay, during torrefaction, may absorb some nutritive principles from the atmosphere that afterwards may be supplied to plants; but the earths are pure metallic oxides, saturated with oxygen; and the tendency of burning is to expel any other volatile principles that they may contain in combination. If the oxide of iron in soils is not saturated with oxygen, torrefaction tends to produce its further union with this principle; and hence, in burning, the color of clay changes to red. The oxide of iron, containing its full proportion of oxygen, has less attraction for acids than the other oxide, and is consequently less likely to be dissolved by any fluid acids in the soil; and it appears in this state to act in the same manner as the earths. A very ingenious author, Naismith (Elements of Agr.), supposes that the oxide of iron, when combined with carbonic acid, is poisonous to plants; and that one use of torrefaction is to expel the carbonic acid from it; but the carbonate of iron is not soluble in water, and is a very inert substance; and a luxuriant crop of cresses has been raised
in a soil composed of one fifth carbonate of iron, and four fifths carbonate of lime. Carbonate of iron abounds in some of the most fertile soils in England, particularly the red hop soil. And there is no theoretical ground for supposing that carbonic acid, which is an essential food of plants, should, in any of its combinations, be poisonous to them; and it is known that lime and magnesia are both noxious to vegetation, unless combined with this principle.

1092. The soils improved by burning are all such as contain too much dead vegetable fibre, and which consequently lose from one third to one half of their weight by incineration; and all such as contain their earthy constituents in an impalpable state of division, i.e. the stiff clays and marls, are improved by burning: but coarse sands, or rich soils containing a just mixture of the earths; and in all cases in which the texture is sufficiently loose, or the organisable matter sufficiently soluble, the process of torrefaction cannot be useful.

1093. All poor siliceous sands are injured by burning. Young in his Essay on Manures, states, "that he found burning injure sand; and the operation is never performed by good cultivators upon siliceous sandy soils, after they have once been brought into cultivation."

SUBSECT. 5. Changing the Condition of Lands, in respect to Water.

1094. The water of the soil where superabundant may be withdrawn, and when deficient supplied: these operations with water are independent of its supply as a manure, or as affording the stimulus of heat or cold.

1095. Stagnant water may be considered as injurious to all the useful classes of plants, by obstructing perspiration and intro-susception, and thus diseasing their roots and submerged parts. Where the surface-soil is properly constituted, and rests on a sub-soil moderately porous, both will hold water by capillary attraction, and what is not so retained will sink into the interior strata by its gravity; but where the sub-soil is retentive, it will resist, or not admit with sufficient rapidity, the percolation of water to the strata below, which accumulating in the surface-soil, till its proportion becomes excessive as a component part, not only carries off the extractive matter, but diseases the plants. Hence the origin of surface-draining, that is, laying land in ridges or beds, or intersecting it with small open gutters.

1096. Springs. Where the upper stratum is porous in some places, and retentive in others, and on a retentive base, the water, in its progress along the porous bed or layer, will be interrupted by the retentive places in a great variety of ways, and there accumulating will burst through the upper surface in the form of springs, which are more injurious than surface-water, as being colder, and generally permanent in their operation. Hence the origin of under-draining in all its varieties of collecting, extracting, and conveying water.

1097. The water of rivers may become injurious to lands on their banks, by too frequently overflowing their surface. In this case the stream may be included by mounds of earth, or other materials impervious to water: and thus aquatic soils rendered dry and fit for useful herbage and aration. The same may be said of lands occasionally overflowed by the sea. Hence the origin of embanking, an art carried to a great extent in Holland and Italy. (See Smewton's Posthumous Works; Sigismundi, Agr. Tosc.; and our article Embankment, in Supp. Encyc. Brit. 1819.)

1098. Irrigation. Plants cannot live without water, any more than they can prosper in soils where it is superabundant; and it is therefore supplied by art on a large scale, either by surface or subterraneous irrigation. In both practices important points are to imitate nature in producing motion, and in applying the water in the mornings or evenings, or under a clouded sky, and also at moderate intervals. The effects of water constantly employed, would, in most cases, be such as attend stagnated water, aquatic soils, or land-springs; and employed in hot sunshine, or after violent heats, it may check evaporation and destroy life, exactly as happens to those who may have bathed in cold spring water after long and violent exercise in a hot day. (Phytologia, xv. 3. 5.)

1099. In surface irrigation the water is conveyed in a system of open channels, which require to be most numerous in such grounds as are under drilled annual crops, and least so in such as are sown in breadths, beds, or ridges, under perennial crops. This mode of watering has existed from time immemorial. The children of Israel are represented as sowing their seed and "watering it with their foot"; that is, as Calmet explains it, raising the water from the Nile by a machine worked by the feet, from which it was conducted in such channels as we have been describing. It is general in the south of France and Italy; but less required in Britain.

1100. Subterraneous irrigation may be effected by a system of drains or covered gutters in the sub-soil, which, proceeding from a main conduit, or other supply, can be charged with water at pleasure. For grounds under the culture of annual plants, this mode would be more convenient, and for all others more economical as to the use of water, than sur-
face irrigation. Where the under-stratum is gravelly, and rests on a retentive stratum, this mode of watering may take place without drains, as it may also on perfectly flat lands, by filling to the brim, and keeping full for several days, surrounding trenches; but the beds or fields between the trenches must not be of great extent. This practice is used in Lombardy on the alluvial lands near the embouchures of the Po. In Lincolnshire the same mode is practised by shutting up the flood-gates of the mouths of the great drains in the dry seasons, and thus damming up the water through all the ramifications of the drainage from the sea to their source. This was first suggested by G. Rennie and Sir Joseph Banks, after the drainage round Boston, completed about 1810. A similar plan, on a smaller scale, had been practised in Scotland, where deep mosses had been drained and cultivated on the surface, but where, in summer, vegetation failed from deficiency of moisture. It was first adopted by J. Smith, (See Essay on the Improvement of Peat-Moss, 1795,) on a farm in Ayrshire, and has subsequently been brought into notice by J. Johnston, the first delineator and professor of Elkinston's system of draining.

1101. Manuring by irrigation. Irrigation with a view to conveying additions to the soil has long been practised, and is an evident imitation of the overflowing of alluvial lands, whether in meadow or aration. In the former case it is called irrigation or flooding, and in the latter, warping. Warping is used chiefly as a mode of enriching the soil by an increase of the alluvial depositions, or warp of rivers, during winter, where the surface is not under crop, and is common on the banks of the Ouse.

1102. The rationale of irrigation is thus given by Sir H. Davy. "In general in nature the operation of water is to bring earthy substances into an extreme state of division. But in the artificial watering of meadows, the beneficial effects depend upon many different causes, some chemical, some mechanical. Water is absolutely essential to vegetation; and when land has been covered by water in the winter, or in the beginning of spring, the moisture that has penetrated deep into the soil, and even the sub-soil, becomes a source of nourishment to the roots of the plants in the summer, and prevents those bad effects that often happen in lands in their natural state, from a long continuance of dry weather. When the water used in irrigation has flowed over a calcareous country, it is generally found impregnated with carbonate of lime; and in this state it tends, in many instances, to ameliorate the soil. Common river water also generally contains a certain portion of organizable matter, which is much greater after rains than at other times; and which exists in the largest quantity when the stream rises in a cultivated country. Even in cases when the water used for flooding is pure, and free from animal or vegetable substances, it acts by causing a more equitable diffusion of nutritive matter existing in the land; and in very cold seasons it preserves the tender roots and leaves of the grass from being affected by frost. Water is of greater specific gravity at 45° Fahrenheit, than at 32°, the freezing point; and hence, in a meadow irrigated in winter, the water immediately in contact with the grass is rarely below 40°, a degree of temperature not at all prejudicial to the living organs of plants. In 1804, in the month of March, the temperature in a water meadow near Hungerford was examined by a very delicate thermometer. The temperature of the air at seven in the morning was 59°. The water was frozen above the grass. The temperature of the soil below the water in which the roots of the grass were fixed, was 43°." Water may also operate usefully in warm seasons by moderating temperature, and thus retarding the over-rapid progress of vegetation. The consequence of this retardation will be greater magnitude and improved texture of the grosser parts of plants, a more perfect and ample development of their finer parts, and, above all, an increase in the size of their fruits and seeds. We apprehend this to be one of the principal uses of flooding rice-grounds in the East; for it is ascertained that the rice-plant will perfect its seeds in Europe, and even in this country, without any water beyond what is furnished by the weather, and the natural moisture of a well constituted soil. "In general, those waters which breed the best fish are the best fitted for watering meadows; but most of the benefits of irrigation may be derived from any kind of water. It is, however, a general principle, that waters containing ferruginous impregnation, though possessed of fertilising effects when applied to a calcareous soil, are injurious on soils that do not effervesce with acids; and that calcareous waters, which are known by the earthy deposit they afford when boiled, are of most use on siliceous soils, or other soils containing no remarkable quantity of carbonate of lime."

Subsect. 6. Changing the Condition of Lands, in respect to Atmospheric Influence.

1103. The influence of the weather on soils may be affected by changing the position of their surface and by sheltering or shading.

1104. Changing the condition of lands, as to solar influence, is but a limited means of improvement; but is capable of being turned to some account in gardening. It is effected by altering the position of their surface, so as that surface may be more or less at right angles to the plane of the sun's rays, according as heat or cold is to be increased.
or diminished. The influence of the sun's rays upon any plane are demonstrated to be as their number and perpendicularity to that plane, neglecting the effects of the atmosphere. Hence one advantage of ridging lands, provided the ridges run north and south; for on such surfaces the rays of the morning sun will take effect sooner on the east side, and those of the afternoon will remain longer in operation on the west side; whilst at mid-day his elevation will compensate, in some degree, for the obliquity of his rays to both sides of the ridge. In culture, on a small scale, ridges or sloping beds for winter-crops may be made south-east and north-west, with their slope to the south, at an angle of forty degrees, and as steep on the north side as the mass can be got to stand; and on the south slope of such ridge, cæteris paribus, it is evident much earlier crops may be produced than on level ground. The north side, however, will be lost during this early cropping; but as early crops are soon gathered, the whole can be laid level in time for a main crop. Hence all the advantage of grounds sloping to the south south-east, or south-west, in point of precocity, and of those sloping to the north for lateness and diminished evaporation. Another advantage of such surfaces is, that they dry sooner after rains, whether by the operation of natural or artificial drainage; or in the case of sloping to the south, by evaporation.

1105. Shelter, whether by walls, hedges, strips of plantation, or trees scattered over the surface, may be considered generally, as increasing or preserving heat, and lessening evaporation from the soil. But if the current of air should be of a higher temperature than that of the earth, screens against wind will prevent the earth from being so soon heated; and from the increased evaporation arising from so great a multiplication of vegetable surface by the trees, more cold will be produced after rains, and the atmosphere kept in a more moist state, than in grounds perfectly naked. When the temperature of a current of air is lower than that of the earth, screens will prevent its carrying off so much heat; but more especially scattered trees, the tops of which will be chiefly cooled whilst the under surfaces of their lower branches reflect back the rays of heat as they radiate from the surface of the soil. Heat in its transmission from one body to another, follows the same laws as light; and, therefore, the temperature of the surface in a forest will, in winter, be considerably higher than that of a similarly constituted soil exposed to the full influence of the weather. The early flowering of plants, in woods and hedges, is a proof of this: but as such soils cannot be so easily heated in summer, and are cooled like others after the sinking in of rains, or the melting of snows, the effect of the reflection as to the whole year is nearly neutralised, and the average temperature of the year of such soils and situations will probably be found not greater than that of open lands.

1106. Shading the ground, whether by umbrageous trees, spreading plants, or covering it with tiles, slates, moss, litter, &c. has a tendency to exclude atmospheric heat and retain moisture. Shading dry loose soils, by covering them with litter, or slates, or tiles, laid round the roots of plants, is found very beneficial.

Subsect. 7. Rotation of Crops.

1107. Growing different crops in succession is a practice which every cultivator knows to be highly advantageous, though its beneficial influence has not yet been fully accounted for by chemists. The most general theory is, that though all plants will live on the same food, as the chemical constituents of their roots and leaves are nearly the same, yet that many species require particular substances to bring their seeds or fruits to perfection, as the analysis of these seeds or fruits often affords substances different from those which constitute the body of the plant. (736.) A sort of rotation may be said to take place in nature, for perennial herbaceous plants have a tendency to extend their circumference, and rot and decay at their centre, where others of a different kind spring up and succeed them. This is more especially the case with travelling roots, as in mint, strawberry, creeping crowfoot, &c.

1108. The rationale of rotation, is thus given by Sir H. Davy. "It is a great advantage in the convertible system of cultivation, that the whole of the manure is employed; and that those parts of it which are not fitted for one crop, remain as nourishment for another. Thus, if the turnip is the first in the order of succession, this crop, manured with recent dung, immediately finds sufficient soluble matter for its nourishment; and the heat produced in fermentation assists the germination of the seed and the growth of the plant. If, after turnips, barley with grass-seeds is sown, then the land, having been little exhausted by the turnip crop, affords the soluble parts of the decomposing manure to the grain. The grasses, rye-grass, and clover remain, which derive a small part only of their organised matter from the soil, and probably consume the gypsum in the manure which would be useless to other crops: these plants, likewise, by their large systems of leaves, absorb a considerable quantity of nourishment from the atmosphere; and when ploughed in at the end of two years, the decay of their roots and leaves affords manure for the wheat crop; and at this period of the course, the woody fibre of the farm-yard manure, which contains the phosphate of lime and the other difficultly soluble parts, is
broken down; and as soon as the most exhausting crop is taken, recent manure is again applied. Peas and beans, in all instances, seem well adapted to prepare ground for wheat; and in some rich lands they are raised in alternate crops for years together. Peas and beans contain a small quantity of a matter analogous to albumen; but it seems that the azote, which forms a constituent part of this matter, is derived from the atmosphere. The dry bean-leaf, when burnt, yields a smell approaching to that of decomposing animal matter; and in its decay in the soil, may furnish principles capable of becoming a part of the gluten in wheat. Though the general composition of plants is very analogous, yet the specific difference in the products of many of them, prove that they must derive different materials from the soil; and though the vegetables having the smallest system of leaves will proportionably most exhaust the soil of common nutritive matter, yet particular vegetables, when their produce is carried off, will require peculiar principles to be supplied to the land in which they grow. Strawberries and potatoes at first produce luxuriantly in virgin mould, recently turned up from pasture; but in a few years they degenerate, and require a fresh soil. Lands, in a course of years, often cease to afford good cultivated grasses; they become (as it is popularly said) tired of them; and one of the probable reasons for this is, the exhaustion of the gypsum contained in the soil.

1109. *The powers of vegetables to exhaust the soil of the principles necessary to their growth, is remarkably exemplified in certain funguses.* Mushrooms are said never to rise in two successive seasons on the same spot; and the production of the phenomena called fairy rings has been ascribed by Dr. Wollaston to the power of the peculiar fungus which forms it, to exhaust the soil of the nutriment necessary for the growth of the species. The consequence is, that the ring annually extends; for no seeds will grow where their parents grew before them; and the interior part of the circle has been exhausted by preceding crops; but where the fungus has died, nourishment is supplied for grass, which usually rises within the circle, coarse, and of a dark green color.

1110. *A rotation is unnecessary, according to Grisenthwaite; and, in a strict chemical sense, what he asserts cannot be denied.* His theory is a refinement on the common idea of the uses of a rotation stated above; but by giving some details of the constituent parts of certain grains and certain manures, he has presented it in a more clear and striking point of view than has hitherto been done. To apply the theory in every case, the constituent parts of all manures and of all plants (1st, their roots and leaves, and, 2dly, their seeds, fruits, or grains,) must be known. In respect to manures this is the case, and it may be said to be in a great degree the case as to the most useful agricultural plants; but, unfortunately for our purpose, the same cannot be said of garden productions in general, though no branch of culture can show the advantage of a rotation of crops more than horticulture, in the practice of which it is found that grounds become tired of particular crops, notwithstanding that manures are applied at pleasure. If the precise effects of a rotation were ascertained, and the ingredients peculiarly necessary to every species pointed out, nothing could be more interesting than the results of experimental trials; and whoever shall point out a simple and economical mode by which the potatoe may be grown successively in the same soil, and produce annually, neglecting the effects of climate, as dry and well-flavored tubers, or nearly so, as they generally produce the first and second years on a new soil, will confer a real benefit on society. That wheat may be grown many years on the same soil by the use of animal manures, or such as contain gluten, Grisenthwaite's theory would justify us in believing chemically; and it ought to be fairly tried by such cultivators as Coke and Curwen. Till this is done in the face of the whole agricultural world, and the produce of every crop, and all the particulars of its culture, accurately reported on annually, the possibility of the thing may be assented to from the premises, but will not be acted on; and, in fact, even the best agricultural chemists do not consider that we are sufficiently advanced in that branch of the science to draw any conclusion, a priori, very much at variance with general opinion and experience.

---

**Of Manures.**

1111. *Every species of matter capable of promoting the growth of vegetables may be considered as manure.* On examining the constituents of vegetables, we shall find that they are composed of oxygen, hydrogen, carbon, and nitrogen, or azote, with a small proportion of saline bodies. It is evident, therefore, that the substances employed as manure should also be composed of these elements, for unless they are, there will be a deficiency in some of the elements in the vegetable itself; and it is probable that such deficiency may prevent the formation of those substances within it, for which its
peculiar organisation is contrived, and upon which its healthy existence depends. The elementary bodies above enumerated are all contained in animal, and the three first in vegetable matters. Sometimes vegetables, though very seldom, contain a small quantity of nitrogen. As certain salts are also constantly found to be present in healthy living vegetables, manures or vegetable food may, consequently, be distinguished into animal, vegetable, and saline. The authors whom we have already mentioned (1029.) as producing the first chemical treatises on soils, were also the first to treat chemically of manures. Of these, the latest in the order of time is Sir H. Davy, from whose highly satisfactory work we shall extract the greater part of this chapter.

SECT. I. Of Manures of Animal and Vegetable Origin.

1112. Decaying animal and vegetable substances constitute by far the most important class of manures, or vegetable food, and may be considered as to the theory of their operation, their specific kinds, and their preservation and application in practice.

1113. The rationale of organic manures is very satisfactorily given by Sir H. Davy, who, after having proved that no solid substances can enter in that state into the plant, explains the manner in which nourishment is derived from vegetable and animal substances.

1114. Vegetable and animal substances deposited in the soil, as is shown by universal experience, are consumed during the process of vegetation; and they can only nourish the plant by affording solid matters capable of being dissolved by water, or gaseous substances capable of being absorbed by the fluids in the leaves of vegetables; but such parts of them as are rendered gaseous, and pass into the atmosphere, must produce a comparatively small effect, for gases soon become diffused through the mass of the surrounding air. The great object, therefore, in the application of manure should be to make it afford as much soluble matter as possible to the roots of the plant; and that in a slow and gradual manner, so that it may be entirely consumed in forming its sap and organised parts.

1115. Mucilaginous, gelatinous, saccharine, oily, and extractive fluids, carbonic acid, and water, are substances that in their unchanged states contain almost all the principles necessary for the life of plants; but there are few cases in which they can be applied as manures in their pure forms; and vegetable manures, in general, contain a great excess of fibrous and insoluble matter, which must undergo chemical changes before they can become the food of plants.

1116. The nature of the changes on these substances; of the causes which occasion them, and which accelerate or retard them; and of the products they afford, have been scientifically stated and explained by our great agricultural chemist. If any fresh vegetable matter which contains sugar, mucilage, starch, or other of the vegetable compounds soluble in water, be moistened, and exposed to air, at a temperature from 55° to 80°, oxygen will soon be absorbed, and carbonic acid formed; heat will be produced, and elastic fluids, principally carbonic acid, gaseous oxide of carbon, and hydro-carbonate will be evolved; a dark-colored liquid, of a slightly sour or bitter taste, will likewise be formed; and if the process be suffered to continue for a time sufficiently long, nothing solid will remain, except earthy and saline matter, colored black by charcoal. The dark-colored fluid formed in the fermentation always contains acetic acid; and when albumen or gluten exists in the vegetable substance, it likewise contains volatile alkali. In proportion as there is more gluten, albumen, or matters soluble in water, in the vegetable substances exposed to fermentation, so in proportion, all other circumstances being equal, will the process be more rapid. Pure woody fibre alone undergoes a change very slowly; but its texture is broken down, and it is easily resolved into new aliments, when mixed with substances more liable to change, containing more oxygen and hydrogen. Volatile and fixed oils, resins, and wax, are more susceptible of change than woody fibre, when exposed to air and water; but much less liable than the other vegetable compounds; and even the most inflammable substances, by the absorption of oxygen, become gradually soluble in water. Animal matters in general are more liable to decompose than vegetable substances; oxygen is absorbed and carbonic acid and ammonia formed in the process of their putrefaction. They produce fritid, compound, elastic fluids and likewise azote: they afford dark-colored acid and oily fluids, and leave a residuum of salts and earths mixed with carbonaceous matter.

1117. The principal animal substances which constitute their different parts, or which are found in their blood, their secretions, or their excrements, are gelatine, fibrine, mucus, fatty, or oily matter, albumen, urea, uric acid, and different other acid, saline, and earthy matters.

1118. General treatment of organic manures. Whenever manures consist principally of
Subsect. 2. Of the different Species of Manures of Animal and Vegetable Origin.

1119. The properties and nature of the manures in common use should be known to every cultivator: for as different manures contain different proportions of the elements necessary to vegetation, so they require a different treatment to enable them to produce their full effects in culture.

1120. All green succulent plants contain saccharine or mucilaginous matter, with woody fibre, and readily ferment. They cannot, therefore, if intended for manure, be used too soon after their death. Hence the advantage of digging or ploughing in green crops, whether natural, of weeds, or sown on purpose; they must not, however, be turned in too deep, otherwise, as Mrs. Ibbetson has shown (Philos. Mag. 1816), fermentation will be prevented by compression and exclusion of air. Green crops should be ploughed in, if it be possible, when in flower, or at the time the flower is beginning to appear, for it is at this period that they contain the largest quantity of easily soluble matter, and that their leaves are most active in forming nutritive matter. Green crops, pond-weeds, the paring of hedges or ditches, or any kind of fresh vegetable matter, require no preparation to fit them for manure. The decomposition slowly proceeds beneath the soil; the soluble matters are gradually dissolved, and the slight fermentation that goes on, checked by the want of a free communication of air, tends to render the woody fibre soluble without occasioning the rapid dissipation of elastic matter. When old pastures are broken up and made arable, not only has the soil been enriched by the death and slow decay of the plants which have left soluble matters in the soil, but the leaves and roots of the grasses, living at the time, and occupying so large a part of the surface, afford saccharine, mucilaginous, and extractive matters, which become immediately the food of the crop, and the gradual decomposition affords a supply for successive years.

1121. Rope-cake, which is used with great success as manure, contains a large quantity of mucilage, some albuminous matter, and a small quantity of oil. This manure should be used recent, and kept as dry as possible before it is applied. It forms an excellent dressing for turnip crops; and is most economically applied by being thrown into the soil at the same time with the seed.

1122. Malt-dust consists chiefly of the infant radicle separated from the grain. Sir H. Davy never made any experiment upon this manure; but has great reason to suppose it must contain saccharine matter, and this will account for its powerful effects. Like rape-cake, it should be used as dry as possible, and its fermentation prevented.

1123. Linseed-cake is too valuable as a food for cattle to be much employed as a manure. The water in which flax and hemp are steeped, for the purpose of obtaining the pure vegetable fibre, has considerable fertilising powers. It appears to contain a substance analogous to albumen, and likewise much vegetable extractive matter. It putrefies very readily. By the watering process, a certain degree of fermentation is absolutely necessary to obtain the flax and hemp in a proper state; the water to which they have been exposed should therefore be used as a manure as soon as the vegetable fibre is removed from it. Washing with soap has been successfully substituted for watering by lie.

1124. Sea-weeds, consisting of different species of fucic, alge, and conferve, are much used as a manure on the sea-coasts of Britain and Ireland. By digesting the common fucus, which is the sea-weed usually most abundant on the coast, in boiling water, one-eighth of a gelatinous substance will be obtained, with characters similar to mucilage. A quantity distilled gave nearly four fifths of its weight of water, but no ammonia; the water had an empyreumatic and slightly sour taste; the ashes contained sea-salt, carbonate of soda, and carbonaceous matter. The gaseous matter afforded was small in quantity, principally carbonic acid, and gaseous oxide of carbon, with a little hydro-carbonate. This manure is transient in its effects, and does not last for more than a single crop; which is easily accounted for from the large quantity of water, or the elements of water, it contains. It decays without producing heat when exposed to the atmosphere, and seems, as it were, to melt down and dissolve away. A large heap has been entirely destroyed in less than two years, nothing remaining but a little black fibrous matter. Some of the finest part of a fucus were suffered to remain in a close jar, containing atmospheric air, for a fortnight: in this time it had become very much shrivelled; the sides
of the jar were lined with dew. The air examined was found to have lost oxygen, and contained carbonic acid gas. Sea-weed is sometimes suffered to ferment before it is used; but this process seems wholly unnecessary, for there is no fibrous matter rendered soluble in the process, and a part of the manure is lost. The best cultivators use it as fresh as it can be procured; and the practical results of this mode of applying it are exactly conformable to the theory of its operation. The carbonic acid formed by its incipient fermentation must be partly dissolved by the water set free in the same process; and thus become capable of absorption by the roots of plants. The effects of the sea-weed, as manure, must principally depend upon this carbonic acid, and upon the soluble mucilage the weed contains; some fucus which had fermented so as to have lost about half its weight, afforded less than one twelfth of mucilaginous matter; from which it may be fairly concluded that some of this substance is destroyed in fermentation.

1125. Dry straw of wheat, oats, barley, beans, and peas, and spoiled hay, or any other similar kind of dry vegetable matter, is, in all cases, useful manure. In general, such substances are made to ferment before they are employed, though it may be doubted whether the practice should be indiscriminately adopted. From 400 grains of dry barley-straw eight grains of matter soluble in water were obtained, which had a brown color, and tasted like mucilage. From 400 grains of wheaten straw were obtained five grains of a similar substance. There can be no doubt that the straw of different crops, immediately ploughed into the ground, affords nourishment to plants; but there is an objection to this method of using straw, from the difficulty of burying long straw, and from its rendering the husbandry foul. When straw is made to ferment, it becomes a more manageable manure; but there is likewise, on the whole, a great loss of nutritive matter. More manure is perhaps supplied for a single crop; but the land is less improved than it would be, supposing the whole of the vegetable matter could be finely divided and mixed with the soil. It is usual to carry straw that can be employed for no other purpose to the dung-hill, to ferment, and decompose; but it is worth experiment, whether it may not be more economically applied when chopped small by a proper machine, and kept dry till it is ploughed in for the use of a crop. In this case, though it would decompose much more slowly, and produce less effect at first, yet its influence would be much more lasting.

1126. Mere woody fibre seems to be the only vegetable matter that requires fermentation to render it nutritive to plants. Tanners' spent bark is a substance of this kind. A. Young, in his excellent Essay on Manure, states, "that spent bark seemed rather to injure than assist vegetation;" which he attributes to the astringent matter that it contains. But, in fact, it is freed from all soluble substances, by the operation of water in the tan-pit; and if injurious to vegetation, the effect is probably owing to its agency upon water, or to its mechanical effects. It is a substance very absorbent and retentive of moisture, and yet not penetrable by the roots of plants.

1127. Inert peaty matter is a substance of the same kind. It remains for years exposed to water and air without undergoing change, and in this state yields little or no nourishment to plants. Woody fibre will not ferment, unless some substances are mixed with it, which act the same part as the mucilage, sugar, and extractive or albuminous matters, with which it is usually associated in herbs and succulent vegetables. Lord Meadowbank has judiciously recommended a mixture of common farm-yard dung for the purpose of bringing peat into fermentation: any putrescible or fermentable substance will answer the end; and the more a substance heats, and the more readily it ferments, the better will it be fitted for the purpose. Lord Meadowbank states, that one part of dung is sufficient to bring three or four parts of peat into a state in which it is fitted to be applied to land; but of course the quantity must vary according to the nature of the dung and of the peat. In cases in which some living vegetables are mixed with the peat, the fermentation will be more readily effected.

1128. Tanners' spent bark, shavings of wood, and saw-dust, will probably require as much dung to bring them into fermentation as the worst kind of peat. Woody fibre may be likewise prepared, so as to become a manure, by the action of lime. It is evident, from the analysis of woody fibre by Gay Lussac and Thenard, (which shows that it consists principally of the elements of water and carbon, the carbon being in larger quantities than in the other vegetable compounds,) that any process which tends to abstract carbonaceous matter from it, must bring it nearer in composition to the soluble principles; and this is done in fermentation by the absorption of oxygen and production of carbonic acid; and a similar effect, it will be shown, is produced by lime.

1129. Wood-ashes, imperfectly formed, that is, wood-ashes containing much charcoal, are said to have been used with success as a manure. A part of their effects may be owing to the slow and gradual consumption of the charcoal, which seems capable, under other circumstances than those of actual combustion, of absorbing oxygen so as to become carbonic acid. In April 1803, some well-burnt charcoal was enclosed by Sir H. Davy, in a tube, half filled with pure water, and half with common air; the tube was hermetically sealed. The tube was opened under pure water, in the spring of 1804, at a time when
the atmospheric temperature and pressure were nearly the same as at the commencement of the experiment. Some water rushed in; and on expelling a little air by heat from the tube, and analysing it, it was found to contain only seven per cent. of oxygen. The water in the tube, when mixed with lime-water, produced a copious precipitate; so that carbonic acid had evidently been formed and dissolved by the water.

1130. Manures from animal substances, in general, require no chemical preparation to fit them for the soil. The great object of the farmer is to blend them with the earthy constituents in a proper state of division, and to prevent their too rapid decomposition.

1131. The entire parts of the muscles of land animals are not commonly used as manure, though there are many cases in which such an application might be easily made. Horses, dogs, sheep, deer, and other quadrupeds that have died accidentally, or of disease, after their skins are separated, are often suffered to remain exposed to the air, or immersed in water, till they are destroyed by birds or beasts of prey, or entirely decomposed; and in this case, most of their organised matter is lost for the land in which they lie, and a considerable portion of it employed in giving off noxious gases to the atmosphere. By covering dead animals with five or six times their bulk of soil, mixed with one part of lime, and suffering them to remain for a few months; their decomposition would impregnate the soil with soluble matters, so as to render it an excellent manure; and by mixing a little fresh quick lime with it at the time of its removal, the disagreeable effluvia would be in a great measure destroyed; and it might be applied in the same way as any other manure to crops.

1132. Fish forms a powerful manure, in whatever state it is applied; but it cannot be ploughed in too fresh, though the quantity should be limited. A Young records an experiment, in which herrings spread over a field, and ploughed in for wheat, produced so rank a crop, that it was entirely laid before harvest. The refuse pilchards in Cornwall are used throughout the county as a manure, with excellent effects. They are usually mixed with sand or soil, and sometimes with sea-weed, to prevent them from raising too luxuriant a crop. The effects are perceived for several years. In the fens of Lincolnshire, Cambridgeshire, and Norfolk, the little fishes called sticklebacks, are caught in the shallow waters in such quantities, that they form a great article of manure in the land bordering on the fens. It is easy to explain the operation of fish as a manure. The skin is principally gelatine; which from its slight state of cohesion, is readily soluble in water; fat or oil is always found in fishes, either under the skin or in some of the viscera; and their fibrous matter contains all the essential elements of vegetable substances.

1133. Amongst oily substances, blubber has been employed as a manure. It is most useful when mixed with clay, sand, or any common soil, so as to expose a large surface to the air, the oxygen of which produces soluble matter from it. Lord Somerville used blubber with great success at his farm in Surrey. It was made into a heap with soil, and retained its powers of fertilising for several successive years. The carbon and hydrogen abounding in oily substances, fully account for their effects; and their durability is easily explained from the gradual manner in which they change by the action of air and water.

1134. Bones are much used as a manure in the neighbourhood of London. After being broken, and boiled for grease, they are sold to the farmer. The more divided they are, the more powerful are their effects. The expense of grinding them in a mill would probably be repaid by the increase of their fertilising powers; and in the state of powder they might be used in the drill husbandry, and delivered with the seed, in the same manner as rape-cake. Bone-dust and bone-shavings, the refuse of the turning manufacture, may be advantageously employed in the same way. The basis of bone is constituted by earthy salts, principally phosphate of lime, with some carbonate of lime and phosphate of magnesia; the easily decomposable substances in bone, are fat, gelatine, and cartilage, which seems of the same nature as coagulated albumen. According to the analysis of Fourcroy and Vauquelin, ox-bones are composed of decomposable animal matter 51; phosphate of lime 37-7, carbonate of lime 10, phosphate of magnesia 1:3;—total 100.

1135. Horn is a still more powerful manure than bone, as it contains a larger quantity of decomposable animal matter. From 500 grains of ox-horn, Hatchett obtained only 1:5 grains of earthy residuum, and not quite half of this was phosphate of lime. The shavings or turnings of horn form an excellent manure, though they are not sufficiently abundant to be in common use. The animal matter in them seems to be of the nature of coagulated albumen, and it is slowly rendered soluble by the action of water. The earthly matter in horn, and still more that in bones, prevents the too rapid decomposition of the animal matter, and renders it very durable in its effects.

1136. Hair, woolen rags, and feathers, are all analogous in composition, and principally consist of a substance similar to albumen united to gelatine. This is shown by the ingenious researches of Hatchett. The theory of their operation is similar to that of bone and horn shavings.

1137. The refuse of the different manufactures of skin and leather form very useful manures; such as the shavings of the currier, furriers' clippings, and the offals of the
tan-yard, and of the glue-maker. The gelatine contained in every kind of skin is in a state fitted for its gradual solution or decomposition; and when buried in the soil, it lasts for a considerable time, and constantly affords a supply of nutritive matter to the plants in its neighbourhood.

1138. Blood contains certain quantities of all the principles found in other animal substances, and is consequently a very good manure. It has been already stated that it contains fibrine; it likewise contains albumen; the red particles in it, which have been supposed by many foreign chemists to be colored by iron in a particular state of combination with oxygen and acid matter, Brande considers as formed of a peculiar animal substance, containing very little iron. The scum taken from the boilers of the sugar-bakers, and which is used as manure, principally consists of bullocks' blood, which has been employed for the purpose of separating the impurities of common brown sugar, by means of the coagulation of its albuminous matter by the heat of the boiler.

1139. The different species of corals, corallines, and sponges, must be considered as substances of animal origin. From the analysis of Hatchett, it appears that all these substances contain considerable quantities of a matter analogous to coagulated albumen; the sponges afford likewise gelatine. According to Merat Guillot, white coral contains equal parts of animal matter and carbonate of lime; red coral 46:3 of animal matter, and 53:5 of carbonate of lime; articulated coralline 51 of animal matter, and 49 of carbonate of lime. These substances are never used as manure in this country, except in cases when they are accidentally mixed with sea-weed; but it is probable that the corallines might be advantageously employed, as they are found in considerable quantity on the rocks, and bottoms of the rocky pools on many parts of our coast, where the land gradually declines towards the sea; and they might be detached by hoes, and collected without much trouble.

1140. Amongst excrementations, animal substances used as manures, urine is the one upon which the greatest number of chemical experiments have been made, and the nature of which is best understood. The urine of the cow contains, according to the experiments of Brande: water 65; phosphate of lime 3; muriate of potassa and ammonia 15; sulphate of potassa 6; carbonates, potassa, and ammonia 4; urea 4.

1141. The urine of the horse, according to Fourcroy and Vauquelin, contains, of carbonate of lime 11, carbonate of soda 9, benzoate of soda 24, muriate of potassa 9, urea 7, water and mucilage 940. In addition to these substances, Brande found in it phosphate of lime. The urine of the ass, the camel, the rabbit, and domestic fowls, have been submitted to different experiments, and their constitution have been found similar. In the urine of the rabbit, in addition to most of the ingredients above mentioned, Vauquelin detected gelatine; and the same chemist discovered uric acid in the urine of domestic fowls. Human urine contains a greater variety of constituents than any other species examined. Urea, uric acid, and another acid similar to it in nature, called rosacic acid, acetic acid, albumen, gelatine, a resinous matter, and various salts are found in it. The human urine differs in composition, according to the state of the body, and the nature of the food and drink made use of. In many cases of disease there is a much larger quantity of gelatine and albumen than usual in the urine; and in diabetes it contains sugar. It is probable that the urine of the same animal must likewise differ according to the different nature of the food and drink used; and this will account for discorances in some of the analyses that have been published on the subject. Urine is very liable to change, and to undergo the putrefactive process; and that of carnivorous animals more rapidly than that of graminivorous animals. In proportion as there is more gelatine and albumen in urine, so in proportion does it putrefy more quickly. The species of urine that contain most albumen, gelatine, and urea, are the best as manures; and all urine contains the essential elements of vegetables in a state of solution. During the putrefaction of urine the greatest part of the soluble animal matter that it contains is destroyed; it should consequently be used as fresh as possible; but if not mixed with solid matter, it should be diluted with water, as, when pure, it contains too large a quantity of animal matter to form a proper fluid nourishment for absorption by the roots of plants.

1142. Putrid urine abounds in ammoniacal salts; and though less active than fresh urine, is a very powerful manure. According to a recent analysis published by Berzelius, 1000 parts of urine are composed of, water 933; urea 30:1; uric acid 1; muriate of ammonia, free lactic acid, lactate of ammonia, and animal matter 17:14. The remainder different salts, phosphates, sulphates, and muriates.

1143. Dung of birds. Amongst excrementitious solid substances used as manures, one of the most powerful is the dung of birds that feed on animal food, particularly the dung of sea-birds. The guano, which is used to a great extent in South America, and which is the manure that fertilises the sterile plains of Peru, is a production of this kind. It exists abundantly, as we are informed by Humboldt, on the small islands in the South Sea, at Chincin, Hlo, Iza, and Arica. Fifty vessels are laden with it annually at Chincin, each of
which carries from 1.500 to 2000 cubical feet. It is used as a manure only in very small quantities; and particularly for crops of maize. Some experiments were made on specimens of guano in 1805. It appeared as a fine brown powder; it blackened by heat, and gave off strong ammoniacal fumes; treated with nitric acid, it afforded uric acid. In 1806, Fourcroy and Vauquelin published an elaborate analysis of guano. They state that it contains a fourth part of its weight of uric acid, partly saturated with ammonia, and partly with potassa; some phosphoric acid combined with the bases, and likewise with lime. Small quantities of sulphate and muriate of potassa, a little fatty matter, and some quartzose sand. It is easy to explain its fertilising properties: from its composition it might be supposed to be a very powerful manure. It requires water for the solution of its soluble matter to enable it to produce its full beneficial effect on crops.

1144. The dung of sea-birds has never been much used as a manure in this country; but it is probable that even the soil of the small islands on our coast much frequented by them would fertilise. Some dung of sea-birds, brought from a rock on the coast of Merionethshire, produced a powerful, but transient effect on grass. The rains in our climate must tend very much to injure this species of manure, where it is exposed to them, soon after its deposition; but it may probably be found in great perfection in caverns or clefts in rocks haunted by cormorants and gulls. Some recent cormorants' dung, when examined, had not at all the appearance of the guano; it was of a greyish-white color; had a very fetid smell, like that of putrid animal matter; when acted on by quick-lime, it gave abundance of ammonia; treated with nitric acid, it yielded uric acid.

1145. Night-soil, it is well known, is a very powerful manure, and very liable to decompose. It differs in composition; but always abounds in substances composed of carbon, hydrogen, azote, and oxygen. From the analysis of Berzelius, it appears that a part of it is always soluble in water; and in whatever state it is used, whether recent or fermented, it supplies abundance of food to plants. The disagreeable smell of night-soil may be destroyed by mixing it with quick-lime; and if exposed to the atmosphere in thin layers, strewed over with quick-lime in fine weather, it speedily dries, is easily pulverised, and in this state, may be used in the same manner as rape-cake, and delivered into the furrow with the seed. The Chinese, who have more practical knowledge of the use and application of manures than any other people existing, mix their night-soil with one third of its weight of a fat marl, make it into cakes, and dry it by exposure to the sun. These cakes, we are informed by the French missionaries, have no disagreeable smell, and form a common article of commerce of the empire. The earth, by its absorbent powers, probably prevents, to a certain extent, the action of moisture upon the dung, and likewise defends it from the effects of air. Desiccated night-soil, in a state of powder, forms an article of internal commerce in France, and is known under the name of pouderette. In London it is mixed with quick-lime, and sold in cakes under the name of Clarke's desiccated compost.

1146. Pigeons' dung comes next in order, as to fertilising power. 100 grains digested in hot water for some hours, produced 22 grains of soluble matter, which afforded abundance of carbonate of ammonia by distillation; and left carbonaceous matter, saline matter, principally common salt, and carbonate of lime as a residuum. Pigeons' dung, when moist, readily ferments, and after fermentation, contains less soluble matter than before; from 100 parts of fermented pigeons' dung, only eight parts of soluble matter were obtained, which gave proportionally less carbonate of ammonia in distillation than recent pigeons' dung. It is evident that this manure should be applied as new as possible; and when dry, it may be employed in the same manner as the other manures capable of being pulverised. The soil in woods, where great flocks of wood-pigeons roost, is often highly impregnated with their dung, and it cannot be doubted, would form a valuable manure. Such soil will often yield ammonia when distilled with lime. In the winter, likewise, it usually contains abundance of vegetable matter, the remains of decayed leaves, and the dung tends to bring the vegetable matter into a state of solution. Manuring was, and still is, in great esteem in Persia.

1147. The dung of domestic fowls approaches very nearly in its nature to pigeons' dung. Uric acid has been found in it. It gives carbonate of ammonia by distillation, and immediately yields soluble matter to water. It is very liable to ferment. The dung of fowls is employed, in common with that of pigeons, by tanners, to bring on a slight degree of putrefaction in skins that are to be used for making soft leather; for this purpose the dung is diffused through water. In this state it rapidly undergoes putrefaction, and brings on a similar change in the skin. The excrements of dogs are employed by the tanner with similar effects. In all cases, the contents of the grainier, as the pit is called in which soft skins are prepared by dung, must form a very useful manure.

1148. Rabbits' dung has never been analysed. It is used with great success as a manure by some farmers, who find it profitable to keep rabbits in such a manner as to preserve
their dung. It is laid on as fresh as possible, and is found better the less it has fermented.

1149. *The dung of cattle*, oxen, and cows, has been chemically examined by Einhof and Thaer. They found that it contained matter soluble in water; and that it gave in fermentation nearly the same products as vegetable substances, absorbing oxygen, and producing carbonic acid gas.

1150. The recent *dung of sheep* and of *deer* affords, when long boiled in water, soluble matters which equal from two to three per cent. of their weight. These soluble substances, procured by solution and evaporation, when examined, contain a very small quantity of matter analogous to animal mucus; and are principally composed of a bitter extract, soluble both in water and in alcohol. They give ammoniacal fumes by distillation, and appear to differ very little in composition. Some blades of grass were watered for several successive days with a solution of these extracts; they evidently became greener in consequence, and grew more vigorously than grass in other respects under the same circumstances. The part of the dung of cattle, sheep, and deer, not soluble in water, appears to be mere woody fibre, and precisely analogous to the residuum of those vegetables that form their food after they have been deprived of all their soluble materials.

1151. *The dung of horses* gives a brown fluid, which, when evaporated, yields a bitter extract, which affords ammoniacal fumes more copiously than that from the dung of oxen.

1152. In the treatment of the pure *dung of cattle, sheep, and horses*, there seems no reason why it should be made to ferment except in the soil, like the other pure dungs; or, if suffered to ferment, it should be only in a very slight degree. The grass, in the neighbourhood of recently voided dung, is always coarse and dark green; some persons have attributed this to a noxious quality in unfermenting dung; but it seems to be rather the result of an excess of food furnished to the plants.

1153. *Street and road dung* and the sweepings of *houses* may be all regarded as composite manures; the constitution of them is necessarily various, as they are derived from a number of different substances. These manures are usually applied in a proper manner, without being fermented.

1154. *Soot*, which is principally formed from the combustion of pit-coal or coal, generally contains likewise substances derived from animal matters. This is a very powerful manure. It affords ammoniacal salts by distillation, and yields a brown extract to hot water, of a bitter taste. It likewise contains an empyreumatic oil. Its great basis is charcoal, in a state in which it is capable of being rendered soluble by the action of oxygen and water. This manure is well fitted to be used in the dry state, thrown into the ground with the seed, and requires no preparation.

**Subsect. 3. Of the fermenting, preserving, and applying of Manures of Animal and Vegetable Origin.**

1155. On the management of *organic manures* depends much of their value as food to plants. The great mass of manures procured by the cultivator are a mixture of animal and vegetable matters, and the great source of supply is the farm or stable yard. Here the excremenitious matter of horses, cattle, swine, and poultry, is mixed with straw, haum, chaff, and various kinds of litter. To what degree should this be fermented before it is applied to the soil? And how can it best be preserved when not immediately wanted?

1156. *A slight incipient fermentation* is undoubtedly of use in the dunghill; for, by means of it a disposition is brought on in the woody fibre to decay and dissolve, when it is carried to the land, or ploughed into the soil; and woody fibre is always in great excess in the refuse of the farm. Too great a degree of fermentation is, however, very prejudicial to the composite manure in the dunghill; it is better that there should be no fermentation at all before the manure is used, than that it should be carried too far. The excess of fermentation tends to the destruction and dissipation of the most useful part of the manure; and the ultimate results of this process are like those of combustion. It is a common practice amongst farmers to suffer the farm-yard dung to ferment till the fibrous texture of the vegetable matter is entirely broken down; and till the manure becomes perfectly cold, and so soft as to be easily cut by the spade. Independent of the general theoretical views unfavorable to this practice, founded upon the nature and composition of vegetable substances, there are many arguments and facts which show that it is prejudicial to the interests of the farmer.

1157. During the *violent fermentation* which is necessary for reducing farm-yard manure to the state in which it is called short muck, not only a large quantity of fluid, but likewise of gaseous matter is lost; so much so, that the dung is reduced one half, or two thirds in weight; and the principal elastic matter disengaged, is carbonic acid with some ammonia; and both these, if retained by the moisture in the soil, as has been stated...
before, are capable of becoming a useful nourishment of plants. In October, 1808, Sir H. Davy filled a large retort capable of containing three pints of water, with some hot fermenting manure, consisting principally of the litter and dung of cattle; he adapted a small receiver to the retort, and connected the whole with a mercurial pneumatic apparatus, so as to collect the condensible and elastic fluids which might rise from the dung. The receiver soon became lined with dew, and drops began in a few hours to trickle down the sides of it. Elastic fluid likewise was generated; in three days thirty-five cubical inches had been formed, which, when analysed, were found to contain twenty-one cubical inches of carbonic acid, the remainder was hydrocarbonate mixed with some azote, probably no more than existed in the common air in the receiver. The fluid matter collected in the receiver at the same time amounted to nearly half an ounce. It had a saline taste, and a disagreeable smell, and contained some acetate and carbonate of ammonia. Finding such products given off from fermenting litter, he introduced the beak of another retort, filled with similar dung, very hot at the time, in the soil amongst the roots of some grass in the border of a garden; in less than a week a very distinct effect was produced on the grass; upon the spot exposed to the influence of the matter disengaged in fermentation, it grew with much more luxuriance than the grass in any other part of the garden.—Besides the dissipation of gaseous matter, when fermentation is pushed to the extreme, there is another disadvantage in the loss of heat, which, if excited in the soil, is useful in promoting the germination of the seed, and in assisting the plant in the first stage of its growth, when it is most feeble and most liable to disease: and the fermentation of manure in the soil must be particularly favorable to the wheat crop, in preserving a genial temperature beneath the surface late in autumn and during winter. Again, it is a general principle in chemistry, that in all cases of decomposition, substances combine much more readily at the moment of their disengagement, than after they have been perfectly formed. And in fermentation beneath the soil the fluid matter produced is applied instantly, even whilst it is warm, to the organs of the plant, and consequently is more likely to be efficient, than in manure that has gone through the process; and of which all the principles have entered into new combinations.

1158. **Checking fermentation by covering.** "There are reasons sufficiently strong," Grisenthwaite observes, "to discourage the practice of allowing dung-heaps to ferment and rot without interruption. It appears that public opinion has slowly adopted the decisions of chemical reasoning, and dung-pies, as they are called, have been formed with a view to save what was before lost; a stratum of mould, sustaining the heap, being placed to receive the fluid parts, and a covering of mould being applied to prevent the dissipation of the aerial, or gaseous products. These purposes and contrivances, unfortunately, like many of the other operations of husbandry, were not directed by scientific knowledge. To cover is so commonly believed to confine, that there is no wonder that the practical cultivator adopted it in this instance from such a consideration. But it is in vain; the elasticity of the gases generated is such as no covering whatever could possibly confine. If it were perfectly compact, it could only preserve as much carbonic acid as is equal to the volume or bulk of air within it; a quantity too incon siderable to be regarded, could it even be saved; but every particle of it must be disengaged, and lost, when the covering is removed."

1159. **Checking fermentation by watering** is sometimes recommended; but this practice is inconsistent with just chemical views. It may cool the dung for a short time; but moisture, as before stated, is a principal agent in all processes of decomposition. Dry fibrous matter will never ferment. Water is as necessary as air to the process; and to supply it to fermenting dung, is to supply an agent which will hasten its decay. In all cases when dung is fermenting, there are simple tests by which the rapidity of the process, and consequently the injury done, may be discovered. If a thermometer, plunged into the dung, does not rise to above one hundred degrees of Fahrenheit, there is little danger of much aceriform matter flying off. If the temperature is higher, the dung should be immediately spread abroad. When a piece of paper, moistened in muriatic acid, held over the steam rising from a dunghill, gives dense fumes, it is a certain test that the decomposition is going too far, for this indicates that volatile alkali is disengaged.

1160. **In favor of the application of farm-yard dung in a recent state,** a great mass of facts may be found in the writings of scientific agriculturists. A. Young, in the Essay on Manures, already quoted, adduces a number of excellent authorities in support of the plan. Many, who doubted, have been lately convinced; and perhaps there is no subject of investigation in which there is such a union of theoretical and practical evidence. Within the last seven years Coke has entirely given up the system formerly adopted on his farm, of applying fermented dung; and his crops have been since as good as they ever were, and his manure goes nearly twice as far. A great objection against slightly fermented dung is, that weeds spring up more luxuriantly where it is applied.
If there are seeds carried out in the dung, they certainly will germinate; but it is seldom that this can be the case to any extent; and if the land is not cleansed of weeds, any kind of manure, fermented or unfermented, will occasion their rapid growth. If slightly fermented farm-yard dung is used as a top-dressing for pastures, the long straws and unfermented vegetable matter remaining on the surface should be removed as soon as the grass begins to rise vigorously, by raking, and carried back to the dunghill; in this case no manure will be lost, and the husbandry will be at once clean and economical. In cases when farm-yard dung cannot be immediately applied to crops, the destructive fermentation of it should be prevented as much as possible: the principles on which this may be effected have been already alluded to. The surface should be defended as much as possible from the oxygen of the atmosphere; a compact marl, or a tenacious clay, offers the best protection against the air; and before the dung is covered over, or, as it were, sealed up, it should be dried as much as possible. If the dung is found at any time to heat strongly, it should be turned over, and cooled by exposure to the air.

1161. The doctrine of the proper application of manures from organised substances, offers an illustration of an important part of the economy of nature, and of the happy order in which it is arranged. The death and decay of animal substances tend to resolve organised forms into chemical constituents; and the pernicious effluvia disengaged in the process seem to point out the propriety of burying them in the soil, where they are fitted to become the food of vegetables. The fermentation and putrefaction of organised substances in the free atmosphere are noxious processes; beneath the surface of the ground they are salutary operations. In this case the food of plants is prepared where it can be used; and that which would offend the senses and injure the health, if exposed, is converted by gradual processes into forms of beauty and of usefulness; the fetid gas is rendered a constituent of the aroma of the flower, and what might be poison becomes nourishment to animals and to man.

1162. To preserve dung for any time, the situation in which it is kept is of importance. It should, if possible, be defended from the sun. To preserve it under sheds would be of great use; or to make the site of a dunghill on the north side of a wall. The floor on which the dung is heaped, should, if possible, be paved with flat stones; and there should be a little inclination from each side towards the centre, in which there should be drains connected with a small well, furnished with a pump, by which any fluid matter may be collected for the use of the land. It too often happens that a dense mucilaginous and extractive fluid is suffered to drain away from the dunghill, so as to be entirely lost to the farm.

**sect. ii. of manures of mineral origin.**

1163. Earthy and saline manures are probably of more recent invention, and doubtless of more uncertain use than those of animal and vegetable origin. The conversion of matter that has belonged to living structures into organised forms, is a process that can be easily understood; but it is more difficult to follow those operations by which earthy and saline matters are consolidated in the fibre of plants, and by which they are made subservient to their functions. These are capable of being materially elucidated by modern chemistry, and shall here be considered as to the theory of their operation, and specific kinds.

**subsect. i. theory of the operation of mineral manures.**

1164. Saline and calcareous substances form the principal fossil manures. Much has been written on lime and common salt, both in the way of speculation and reasoning from facts, which, from want of chemical knowledge, has turned to no useful account, and cultivators till very lately contented themselves with stating that these substances acted as stimulii to the soil, something like condiments to the digestive organs of animals. Even chemists themselves are not yet unanimous in all their opinions; but still the result of their enquiries will be found of great benefit to the scientific cultivator.

1165. Various opinions exist as to the rationale of the operation of mineral manures. "Some enquirers," Sir H. Davy observes, "adopting that sublime generalisation of the ancient philosophers, that matter is the same in essence, and that the different substances, considered as elements by chemists, are merely different arrangements of the same indestructible particles, have endeavoured to prove, that all the varieties of the principles found in plants, may be formed from the substances in the atmosphere; and that vegetable life is a process in which bodies that the analytical philosopher is unable to change or to form, are constantly composed and decomposed. But the general results of experiments are very much opposed to the idea of the composition of the earths, by plants, from any of the elements found in the atmosphere, or in water; and there are various facts contradictory to the idea. Jacquin states, that the ashes of glass-wort (Sal-
sola soda), when it grows in inland situations, afford the vegetable alkali; when it grows on the sea-shore, where compounds which afford the fossil or marine alkali are more abundant, it yields that substance. Du Hamel found that plants which usually grow on the sea-shore, made small progress when planted in soils containing little common salt. The sun-flower, when growing in lands containing no nitre, does not afford that substance; though when watered by a solution of nitre, it yields nitre abundantly. The tables of De Saussure show that the ashes of plants are similar in constitution to the soils in which they have vegetated. De Saussure made plants grow in solutions of different salts; and he ascertained that, in all cases, certain portions of the salts were absorbed by the plants, and found unaltered in their organs. Even animals do not appear to possess the power of forming the alkaline and earthy substances. Dr. Fordyce found, that when canary-birds, at the time they were laying eggs, were deprived of access to carbonate of lime, their eggs had soft shells; and if there is any process for which nature may be conceived most likely to supply resources of this kind, it is that connected with the reproduction of the species.

1166. It seems a fair conclusion, as the evidence on the subject now stands, that the different earths and saline substances found in the organs of plants, are supplied by the soils in which they grow; and in no cases composed by new arrangements of the elements in air or water. What may be our ultimate view of the laws of chemistry, or how far our ideas of elementary principles may be simplified, it is impossible to say. We can only reason from facts. We cannot imitate the powers of composition belonging to vegetable structures; but at least we can understand them: and as far as our researches have gone, it appears that in vegetation compound forms are uniformly produced from simple ones; and the elements in the soil, the atmosphere and the earth absorbed and made parts of beautiful and diversified structures. The views which have been just developed lead to correct ideas of the operation of those manures which are not necessarily the result of decayed organised bodies, and which are not composed of different proportions of carbon, hydrogen, oxygen, and azote. They must produce their effect, either by becoming a constituent part of the plant, or by acting upon its more essential food, so as to render it more fitted for the purposes of vegetable life.

Subsect. 2. Of the different Species of Mineral Manures.

1167. Alkaline earths, or alkalies and their combinations, which are found unmixed with the remains of any organised beings, are the only substances which can with propriety be called fossil manures. The only alkaline earths which have been hitherto applied in this way are lime and magnesia; though potassa and soda, the two fixed alkalies, are both used to a limited extent in certain of their chemical compounds.

1168. The most common form in which lime is found on the surface of the earth, is in a state of combination with carbonic acid or fixed air. If a piece of limestone or chalk be thrown into a fluid acid, there will be an effervescence. This is owing to the escape of the carbonic acid gas. The lime becomes dissolved in the liquor. When limestone is strongly heated, the carbonic acid gas is expelled, and then nothing remains but the pure alkaline earth; in this case there is a loss of weight; and if the fire has been very high, it approaches to one half the weight of the stone; but in common cases, limestones, if well dried before burning, do not lose much more than 35 to 40 per cent., or from seven to eight parts out of twenty.

1169. When burnt lime is exposed to the atmosphere, in a certain time it becomes mild, and is the same substance as that precipitated from lime-water; it is combined with carbonic acid gas. Quick-lime, when first made, is caustic and burning to the tongue, renders vegetable blues green, and is soluble in water; but when combined with carbonic acid, it loses all these properties, its solubility, and its taste: it regains its power of effervescing, and becomes the same chemical substance as chalk or limestone. Very few limestones or chalks consist entirely of lime and carbonic acid. The statuary marbles, or certain of the rhomboidal spars, are almost the only pure species; and the different properties of limestones, both as manures and cements, depend upon the nature of the ingredient mixed in the limestone; for the true calcareous element, the carbonate of lime, is uniformly the same in nature, properties, and effects, and consists of one proportion of carbonic acid 41 4, and one of lime 55. When a limestone does not copiously effervesce in acids, and is sufficiently hard to scratch glass, it contains siliceous, and probably aluminous earth. When it is deep brown or red, or strongly colored, of any of the shades of brown or yellow, it contains oxide of iron. When it is not sufficiently hard to scratch glass, but effervesces slowly, and makes the acid in which it effervesces milky, it contains magnesia. And when it is black, and emits a fetid smell if rubbed, it contains coaly or bituminous matter. Before any opinion can be formed of the manner in which the different ingredients in limestones modify their properties, it will be necessary to consider the operation of pure lime as a manure.
1170. Quick-lime, in its pure state, whether in powder, or dissolved in water, is injurious to plants. In several instances grass has been killed by watering it with lime-water. But lime, in its state of combination with carbonic acid, is a useful ingredient in soils. Calcareous earth is found in the ashes of the greater number of plants; and exposed to the air, lime cannot long continue caustic, for the reasons that were just now assigned, but soon becomes united to carbonic acid. When newly-burnt lime is exposed to air, it soon falls into powder; in this case it is called slacked lime; and the same effect is immediately produced by throwing water upon it, when it heats violently, and the water disappears. Slacked lime is merely a combination of lime, with about one third of its weight of water; i.e. fifty-five parts of lime absorb seventeen parts of water; and in this case it is composed of a definite proportion of water, and is called by chemists hydrate of lime; and when hydrate of lime becomes carbonate of lime by long exposure to air, the water is expelled, and the carbonic acid gas takes its place. When lime, whether freshly burnt or slacked, is mixed with any moist fibrous vegetable matter, there is a strong action between the lime and the vegetable matter, and they form a kind of compost together, of which a part is usually soluble in water. By this kind of operation, lime renders matter which was before comparatively inert, nutritious; and as charcoal and oxygen abound in all vegetable matters, it becomes at the same time converted into carbonate of lime.

1171. Mild lime, powdered limestone, marls, or chalks have no action of this kind upon vegetable matter; they prevent the too rapid decomposition of substances already dissolved; but they have no tendency to form soluble matters. It is obvious from these circumstances, that the operation of quick-lime, and marl, or chalk, depends upon principles altogether different. Quick-lime, in being applied to land, tends to bring any hard vegetable matter that it contains into a state of more rapid decomposition and solution, so as to render it a proper food for plants. Chalk and marl, or carbonate of lime, will only improve the texture of the soil, or its relation to absorption; it acts merely as one of its earthly ingredients. Chalk has been recommended as a substance calculated to correct the sourness of land. It would surely have been a wise practice to have previously ascertained the certainty of this existence of acid, and to have determined its nature, in order that it might be effectually removed. The fact really is, that no soil was ever yet found to contain any notable quantity of uncombined acid. The acetic and carbonic acids are the only two that are likely to be generated by any spontaneous decomposition of animal or vegetable bodies, and neither of these has any fixity when exposed to the air. Chalk having no power of acting on animal and vegetable substances, can be no otherwise serviceable to land than as it alters its texture. Quick-lime, when it becomes mild, operates in the same manner as chalk; but in the act of becoming mild, it prepares soluble out of insoluble matter. Bouillon la Grange says, that gelatine oxygénisé becomes insoluble, and vegetable extract we know becomes so from the same cause; now lime has the property of attracting oxygen, and, consequently, of restoring the property of solubility to those substances which have been deprived of it, from a combination with oxygen. Hence the uses of lime on peat lands, and on all soils containing an excess of vegetable insoluble matter. (Grisenthwaite.)

1172. Effect of lime on wheat crops. When lime is employed upon land where there is present any quantity of animal matter, it occasions the evolution of a quantity of ammonia, which may, perhaps, be imbided by the leaves of plants, and afterwards undergo some change so as to form glutin. It is upon this circumstance that the operation of lime in the preparation for wheat crops depends; and its efficacy in fertilising peat, and in bringing into a state of cultivation all soils abounding in hard roots, or dry fibres, or inert vegetable matter.

1173. General principles for applying lime. The solution of the question whether quick-lime ought to be applied to a soil, depends upon the quantity of inert vegetable matter that it contains. The solution of the question, whether marl, mild lime, or powdered limestone ought to be applied, depends upon the quantity of calcareous matter already in the soil. All soils are improved by mild lime, and ultimately by quick-lime, which do not effervescence with acids; and sands more than clays. When a soil, deficient in calcareous matter, contains much soluble vegetable manure, the application of quick-lime should always be avoided, as it either tends to decompose the soluble matters by uniting to their carbon and oxygen so as to become mild lime, or it combines with the soluble matters, and forms compounds having less attraction for water than the pure vegetable substance. The case is the same with respect to most animal manures; but the operation of the lime is different in different cases, and depends upon the nature of the animal matter. Lime forms a kind of insoluble soap with oily matters, and then gradually decomposes them by separating from them oxygen and carbon. It combines likewise with the animal acids, and probably assists their decomposition by abstracting carbonaceous matter from them combined with oxygen; and consequently it must render them less nutritious. It tends to diminish likewise the nutritive powers of albumen from the same causes; and always
destroys, to a certain extent, the efficacy of animal manures; either by combining with certain of their elements, or by giving to them new arrangements. Lime should never be applied with animal manures, unless they are too rich, or for the purpose of preventing noxious effluvia. It is injurious when mixed with any common dung, and tends to render the extractive matter insoluble.

1174. **Lime promotes fermentation.** In those cases in which fermentation is useful to produce nutriment from vegetable substances, lime is always efficacious. Some moist tanners’ spent bark was mixed with one fifth of its weight of quick-lime, and suffered to remain together in a close vessel for three months; the lime had become colored, and was effervescent; when water was boiled upon the mixture, it gained a tint of fawn-color, and by evaporation furnished a fawn-colored powder, which must have consisted of lime united to vegetable matter, for it burnt when strongly heated, and left a residuum of mild lime.

1175. **Different kinds of limestones have different effects.** The limestones containing alumina and silica are less fitted for the purposes of manure than pure limestones; but the lime formed from them has no noxious quality. Such stones are less efficacious, merely because they furnish a smaller quantity of quick-lime. There is very seldom any considerable portion of coaly matter in bituminous limestones; never as much as five parts in 100; but such limestones make very good lime. The carbonaceous matter can do no injury to the land, and may, under certain circumstances, become a food of the plant.

1176. **The subject of the application of the magnesian limestone is one of great interest.** It had been long known to farmers in the neighbourhood of Doncaster, that lime made from a certain limestone applied to the land, often injured the crops considerably. Tennant, in making a series of experiments upon this peculiar calcareous substance, found that it contained magnesia; and on mixing some calcined magnesia with soil, in which he sowed different seeds, he found that they either died or vegetated in a very imperfect manner, and the plants were never healthy. And with great justice and ingenuity he referred the bad effects of the peculiar limestone to the magnesian earth it contains.

1177. **Magnesian limestone is used with good effect in some cases.** Magnesia has a much weaker attraction for carbonic acid than lime, and will remain in the state of caustic or calcined magnesia for many months, though exposed to the air. And as long as any caustic lime remains, the magnesia cannot be combined with carbonic acid, for lime instantly attracts carbonic acid from magnesia. When a magnesian limestone is burnt, the magnesia is deprived of carbonic acid much sooner than the lime; and if there is not much vegetable or animal matter in the soil to supply by its decomposition carbonic acid, the magnesia will remain for a long while in the caustic state; and in this state acts as a poison to certain vegetables. And that more magnesian lime may be used upon rich soils, seems to be owing to the circumstance that the decomposition of the manure in them supplies carbonic acid. And magnesia, in its mild state, i.e. fully combined with carbonic acid, seems to be always a useful constituent of soils. Carbonate of magnesia (procured by boiling the solution of magnesia in supercarbonate of potassa,) was thrown upon grass, and upon growing wheat and barley, so as to render the surface white; but the vegetation was not injured in the slightest degree. And one of the most fertile parts of Cornwall, the Lizard, is a district in which the soil contains mild magnesian earth. It is obvious, from what has been said, that lime from the magnesian limestone may be applied in large quantities to peats; and that where lands have been injured by the application of too large a quantity of magnesian lime, peat will be a proper and efficient remedy.

1178. **A simple test of magnesia in a limestone is its slight effervescence with acids, and its rendering diluted nitric acid, or aqua fortis, milky.** From the analysis of Tennant, it appears to contain from 20:3 to 22:5 magnesia; 29:5 to 31:7 lime; 47:2 carbonic acid; 0:8 clay and oxide of iron. Magnesia limestones are usually colored brown or pale yellow. They are found in Somersetshire, Leicestershire, Derbyshire, Shropshire, Durham, and Yorkshire; and in many parts of Ireland, particularly near Belfast. In general, when limestones are not magnesian, their purity will be indicated by their loss of weight in burning; the more they lose, the larger is the quantity of calcareous matter they contain. The magnesian limestones contain more carbonic acid than the common limestones; and I have found all of them lose more than half their weight by calcination.

1179. **Gypsum.** Besides being used in the forms of lime and carbonate of lime, calcareous matter is applied for the purposes of agriculture in other combinations. One of these bodies is gypsum or sulphate of lime. This substance consists of sulphuric acid (the same body that exists combined with water in oil of vitriol,) and lime; and when dry it is composed of 55 parts of lime and 75 parts of sulphuric acid. Common gypsum or selenite, such as that found at Shotover Hill, near Oxford, contains, besides sulphuric acid and lime, a considerable quantity of water; and its composition may be thus
expressed: sulphuric acid one proportion 75; lime one proportion 55; water two proportions 34.

1180. The nature of gypsum is easily demonstrated; if oil of vitriol be added to quick-lime, there is a violent heat produced; when the mixture is ignited, water is given off; and gypsum alone is the result, if the acid has been used in sufficient quantity; and gypsum mixed with quick-lime, if the quantity has been deficient. Gypsum, free from water, is sometimes found in nature, when it is called anhydrous selenite. It is distinguished from common gypsum by giving off no water when heated. When gypsum, free from water, or deprived of water by heat, is made into a paste with water, it rapidly sets by combining with that fluid. Plaster of Paris is powdered dry gypsum, and its properties as a cement, and its use in making casts, depends upon its solidifying a certain quantity of water, and making with it a coherent mass. Gypsum is soluble in about 500 times its weight of cold water, and is more soluble in hot water; so that when water has been boiled in contact with gypsum, crystals of this substance are deposited as the water cools. Gypsum is easily distinguished by its properties of affording precipitates to solutions of oxalates and of barytic salts. In America it is employed with signal success; it has been advantageously used in Kent, but in most counties of England it has failed, though tried in various ways, and upon different crops.

1181. Very discordant notions have been formed as to the mode of operation of gypsum. It has been supposed by some persons to act by its power of attracting moisture from the air; but this agency must be comparatively insignificant. When combined with water, it retains that fluid too powerfully to yield it to the roots of the plant, and its adhesive attraction for moisture is inconceivable; the small quantity in which it is used likewise is a circumstance hostile to this idea. It has been erroneously said that gypsum assists the putrefaction of animal substances, and the decomposition of manure.

1182. The ashes of saintfoin, clover, and ryegrass, afford considerable quantities of gypsum; and the substance probably is intimately combined as a necessary part of their woody fibre. If this be allowed, it is easy to explain the reason why it operates in such small quantities; for the whole of a clover crop, or saintfoin crop, on an acre, according to estimation, would afford by incineration only three or four bushels of gypsum. The reason why gypsum is not generally efficacious, is probably because most cultivated soils contain it in sufficient quantities for the use of the grasses. In the common course of cultivation, gypsum is furnished in the manure; for it is contained in stable dung, and in the dung of all cattle fed on grass; and it is not taken up in corn crops, or crops of peas and beans, and in very small quantities in turnip crops; but where lands are exclusively devoted to pasturage and hay, it will be continually consumed. Should these statements be confirmed by future enquiries, a practical inference of some value may be derived from them. It is possible that lands which have ceased to bear good crops of clover, or artificial grasses, may be restored by being manured with gypsum. This substance is found in Oxfordshire, Gloucestershire, Somersetshire, Derbyshire, Yorkshire, &c. and requires only pulvérisation for its preparation.

1183. Upon the use of sulphate of iron, or green vitriol, which is a salt produced from peat in Bedfordshire, some very interesting documents have been produced by Dr. Pearson; and there is little doubt that the peat salt and the vitriolic water acted chiefly by producing gypsum. The soils on which both are efficacious are calcareous; and sulphate of iron is decomposed by the carbonate of lime in such soils. The sulphate of iron consists of sulphuric acid and oxide of iron, and is an acid and a very soluble salt; when a solution of it is mixed with carbonate of lime, the sulphuric acid quits the oxide of iron to unite to the lime, and the compounds produced are insipid and comparatively insoluble.

1184. Vitriolic impregnations in soils where there is no calcareous matter are injurious; but it is probably in consequence of their supplying an excess of ferruginous matter to the sap. Oxide of iron, in small quantities, forms a useful part of soils; it is found in the ashes of plants, and probably is hurtful only in its acid combinations. The ashes of all peats do not afford gypsum. In general, when a recent peat-ash emits a strong smell, resembling that of rotten eggs, when acted upon by vinegar, it will furnish gypsum.

1185. Phosphate of lime is a combination of phosphoric acid and lime, one proportion of each. It is a compound insoluble in pure water, but soluable in water containing any acid matter. It forms the greatest part of calcined bones. It exists in most excrementitious substances, and is found both in the straw and grain of wheat, barley, oats, and rye; and likewise in beans, peas, and tares. It exists in some places in these islands native, but only in very small quantities. Phosphate of lime is generally conveyed to the land in the composition of other manure, and it is probably necessary to corn crops and other white crops.

1186. Bone-ashes calcined and ground to powder will probably be found useful on arable lands containing much vegetable matter, and may perhaps enable soft peats to produce
wheat; but the powdered bone in an uncalcined state is much to be preferred in all cases when it can be procured.

1187. The saline compounds of magnesia will require very little discussion as to their uses as manures. In combination with sulphuric acid, magnesia forms a soluble salt. This substance, it is stated by some enquirers, has been found of use as a manure; but it is not found in nature in sufficient abundance, nor is it capable of being made artificially sufficiently cheap to be of useful application in the common course of husbandry.

1188. Wood-ashes consist principally of the vegetable alkali united to carbonic acid; and as this alkali is found in almost all plants, it is not difficult to conceive that it may form an essential part of their organs. The general tendency of the alkalis is to give solubility to vegetable matters; and in this way they may render carbonaceous and other substances capable of being taken up by the tubes in the radical fibres of plants. The vegetable alkali likewise has a strong attraction for water, and even in small quantities, may tend to give a due degree of moisture to the soil, or to other manures; though this operation, from the small quantities used or existing in the soil, can be only of a secondary kind.

1189. The mineral alkali or soda is found in the ashes of sea-weed, and may be procured by certain chemical agencies from common salt. Common salt consists of the metal named sodium, combined with chlorine; and pure soda consists of the same metal united to oxygen. When water is present, which can afford oxygen to the sodium, soda may be obtained in several modes from salt. The same reasoning will apply to the operation of the pure mineral alkali, or the carbonated alkali, as to that of the vegetable alkali; and when common salt acts as a manure, it is probably by entering into the composition of the plant in the same manner as gypsum, phosphate of lime, and the alkales. Sir John Pringle has stated, that salt in small quantities assists the decomposition of animal and vegetable matter. This circumstance may render it useful in certain soils. Common salt, likewise, is offensive to insects. In small quantities it is sometimes a useful manure, and it is probable that its efficacy depends upon many combined causes. Some persons have argued against the employment of salt; because when used in large quantities, it either does no good, or renders the ground sterile; but this is a very unfair mode of reasoning. That salt in large quantities rendered land barren, was known long before any records of agricultural science existed. We read in the Scriptures, that Abimelech took the city of Shechem, "and beat down the city, and sowed it with salt;" that the soil might be for ever unfruitful. Virgil reprobrates a salt soil; and Pliny, though he recommends giving salt to cattle, yet affirms, that when strewn over land it renders it barren. But these are not arguments against a proper application of it. Refuse salt in Cornwall, which, however, likewise contains some of the oil and exuvia of fish, has long been known as an admirable manure. And the Cheshire farmers contend for the benefit of the peculiar produce of their country. It is not unlikely, that the same causes influence the effects of salt, as those which act in modifying the operation of gypsum. Most lands in this island, particularly those near the sea, probably contain a sufficient quantity of salt for all the purposes of vegetation; and in such cases the supply of it to the soil will not only be useless, but may be injurious. In great storms the spray of the sea has been carried more than fifty miles from the shore; so that from this source salt must be often supplied to the soil. Salt is found in almost all sandstone rocks, and it must exist in the soil derived from these rocks. It is a constituent likewise of almost every kind of animal and vegetable manure.

1190. Other compounds. Besides these compounds of the alkaline earths and alkalis, many others have been recommended for the purposes of increasing vegetation; such as nitre, or the nitrous acid combined with potassa. Sir Kenelm Digby states, that he made barley grow very luxuriantly by watering it with a very weak solution of nitre; but he is too speculative a writer to awaken confidence in his results. This substance consists of one proportion of azote, six of oxygen, and one of potassium; and it is not unlikely that it may furnish azote to form albumen or gluten in those plants that contain them; but the nitrous salts are too valuable for other purposes to be used as manures. Dr. Home states, that sulphate of potassa, which was just now mentioned as found in the ashes of some peats, is a useful manure. But Naismith (Elements of Agriculture, p. 78.) questions his results; and quotes experiments hostile to his opinion, and, as he conceives, unfavorable to the efficacy of any species of saline manure. Much of the discordance of the evidence relating to the efficacy of saline substances depends upon the circumstance of their having been used in different proportions, and, in general, in quantities much too large.

1191. Solutions of saline substances were used twice a week, in the quantity of two ounces, on spots of grass and corn, sufficiently remote from each other to prevent any interference of results. The substances tried were super-carbonate, sulphate, acetate, nitrate, and muriate of potassa; sulphate of soda; sulphate, nitrate, muriate, and carbonate of ammonia. It was found, that in all cases when the quantity of the salt equalled one thirtieth
part of the weight of the water, the effects were injurious; but least so in the instances of the carbonate, sulphate, and muriate of ammonia. When the quantities of the salts were one three-hundredth part of the solution, the effects were different. The plants watered with the solutions of the sulphates grew just in the same manner as similar plants watered with rain-water. Those acted on by the solution of nitre, acetate, and super-carbonate of potassa, and muriate of ammonia, grew rather better. Those treated with the solution of carbonate of ammonia grew most luxuriantly of all. This last result is what might be expected, for carbonate of ammonia consists of carbon, hydrogen, azote, and oxygen. There was, however, another result which was not anticipated; the plants watered with solution of nitrate of ammonia did not grow better than those watered with rain-water. The solution reddened litmus paper; and probably the free acid exerted a prejudicial effect, and interfered with the result.

1192. Soot doubtless owes part of its efficacy to the ammoniacal salts it contains. The liquor produced by the distillation of coal contains carbonate and acetate of ammonia, and is said to be a very good manure.

1193. Soapers' waste has been recommended as a manure, and it has been supposed that its efficacy depended upon the different saline matters it contains; but their quantity is very minute indeed, and its principal ingredients are mild lime and quick-lime. In the soapers' waste, from the best manufactories, there is scarcely a trace of alkali. Lime, moistened with sea-water, affords more of this substance, and is said to have been used in some cases with more benefit than common lime.

1194. The result of Sir H. Davy's discussion as to the extent of the effects of saline substances on vegetation, is, that except the ammoniacal compounds, or the compounds containing nitric, acetic, and carbonic acid, none of them can afford by their decomposition any of the common principles of vegetation—carbon, hydrogen, and oxygen. The alkaline sulphates and the earthy muriates are so seldom found in plants, or are found in such minute quantities, that it can never be an object to apply them to the soil. The earthy and alkaline substances seem never to be formed in vegetation; and there is every reason to believe, that they are never decomposed; for, after being absorbed, they are found in their ashes. The metallic bases of them cannot exist in contact with aqueous fluids; and these metallic bases, like other metals, have not as yet been resolved into any other forms of matter by artificial processes; they combine readily with other elements; but they remain indestructible, and can be traced undiminished in quantity, through their diversified combinations.

---

**Chap. III.**

Of the Agency of Heat, Light, Electricity, and Water, in Vegetable Culture.

1195. The particular agency of heat, light, and water in vegetation and culture has been so frequently illustrated, that it only remains to give a general idea of their natures, and to offer some remarks on electricity.

**Sect. I. Of Heat and Light.**

1196. The heat of the sun is the cause of growth, and its light the cause of maturity, in the vegetable kingdom. This is universally acknowledged: animals will live without or with very little light; but no plants whatever can exist for any time without the presence of this element. The agency of electricity in vegetation is less known.

1197. Two opinions are current respecting the nature of heat. By some philosophers it is conceived to be a peculiar subtle fluid, of which the particles repel each other, but have a strong attraction for the particles of other matter. By others it is considered as a motion or vibration of the particles of matter, which is supposed to differ in velocity in different cases, and thus to produce the different degrees of temperature. Whatever decision be ultimately made respecting these opinions, it is certain that there is matter moving in the space between us and the heavenly bodies capable of communicating heat; the motions of which are rectilinear: thus the solar rays produce heat in acting on the surface of the earth. The beautiful experiments of Dr. Herschel have shown that there are rays transmitted from the sun which do not illuminate, and which yet produce more heat than the visible rays; and Ritter and Dr. Wollaston have shown that there are other invisible rays distinguished by their chemical effects.

1198. Heat is radiated by the sun to the earth, and if suffered to accumulate, Dr. Wells observes, would quickly destroy the present constitution of our globe. This evil is prevented by the radiation of heat from the earth to the heavens, during the night, when it receives from them little or no heat in return. But, through the wise economy of means, which is witnessed in all the operations of nature, the prevention of this evil is made the source of great positive good. For the surface of the earth, having thus become colder
than the neighbouring air, condenses a part of the watery vapor of the atmosphere into dew, the utility of which is too manifest to require elucidation. This fluid appears chiefly where it is most wanted, on herbage and low plants, avoiding, in great measure, rocks, bare earth, and considerable masses of water. Its production, too, tends to prevent the injury that might arise from its own cause; since the precipitation of water, upon the tender parts of plants, must lessen the cold in them, which occasions it. The prevention, either wholly or in part, of cold, from radiation, in substances on the ground, by the interposition of any solid body between them and the sky, arises in the following manner: the lower body radiates its heat upwards, as if no other intervened between it and the sky; but the loss, which it hence suffers, is more or less compensated by what is radiated to it, from the body above, the under surface of which possesses always the same, or very nearly the same temperature as the air. The manner in which clouds prevent, or occasion to be small, the appearance of a cold at night, upon the surface of the earth, is by radiating heat to the earth, in return for that which they intercept in its progress from the earth towards the heavens. For although, upon the sky becoming suddenly cloudy during a calm night, a naked thermometer, suspended in the air, commonly rises 2 or 3 degrees; little of this rise is to be attributed to the heat evolved by the condensation of watery vapor in the atmosphere, for the heat so extricated must soon be dissipated; whereas the effect of greatly lessening, or preventing altogether, the appearance of a superior cold on the earth to that of the air, will be produced by a cloudy sky, during the whole of a long night.

1199. Dense clouds, near the earth, reflect back the heat they receive from it by radiation. But similarly dense clouds, if very high, though they equally intercept the communication of the earth with the sky, yet being, from their elevated situation, colder than the earth, will radiate to it less heat than they receive from it, and may, consequently, admit of bodies on its surface becoming several degrees colder than the air. Islands, and parts of continents close to the sea, being, by their situation, subject to a cloudy sky, will, from the smaller quantity of heat lost by them through radiation to the heavens, at night, in addition to the reasons commonly assigned, be less cold in winter, than countries considerably distant from any ocean.

1200. Fogs, like clouds, will arrest heat, which is radiated upwards by the earth, and if they be very dense, and of considerable perpendicular extent, may remit to it as much as they receive. Fogs do not, in any instance, furnish a real exception to the general rule, that whatever exists in the atmosphere, capable of stopping or impeding the passage of radiant heat, will prevent or lessen the appearance at night of a cold on the surface of the earth, greater than that of the neighbouring air. The water deposited upon the earth, during a fog at night, may sometimes be derived from two different sources, one of which is a precipitation of moisture from a considerable part of the atmosphere, in consequence of its general cold; the other, a real formation of dew, from the condensation, by means of the superficial cold of the ground, of the moisture of that portion of the air, which comes in contact with it. In such a state of things, all bodies will become moist, but those especially which most readily attract dew in clear weather.

1201. When bodies become cold by radiation, the degree of effect observed must depend, not only on their radiating power, but in part also on the greater or less ease with which they can derive heat, by conduction, from warmer substances in contact with them. Bodies, exposed in a clear night to the sky, must radiate as much heat to it during the prevalence of wind, as they would do if the air were altogether still. But in the former case, little or no cold will be observed upon them above that of the atmosphere, as the frequent application of warm air must quickly return a heat equal, or nearly so, to that which they had lost by radiation. A slight agitation of the air is sufficient to produce some effect of this kind; though, as has already been said, such an agitation, when the air is very pregnant with moisture, will render greater the quantity of dew, one requisite for a considerable production of this fluid being more increased by it, than another is diminished.

1202. It has been remarked, that the hurtful effects of cold occur chiefly in hollow places. If this be restricted to what happens on serene and calm nights, two reasons from different sources are to be assigned for it. The first is, that the air being stiller in such a situation, than in any other, the cold, from radiation, in the bodies which it contains, will be less diminished by renewed applications of warmer air; the second, that from the longer continuance of the same air in contact with the ground, in depressed places than in others, less dew will be deposited, and therefore less heat extricated during its formation.

1203. An observation closely connected with the preceding, namely, that in clear and still nights, frosts are less severe upon hills, than in neighbouring plains, has excited more attention, chiefly from its contradicting what is commonly regarded an established fact, that the cold of the atmosphere always increases with the distance from the earth. But on the contrary the fact is certain, that in very clear and still nights, the air near to the
earth is colder than that which is more distant from it, to the height at least of 220 feet, this being the greatest to which experiments relate. If then a hill be supposed to rise from a plain to the height of 220 feet, having upon its summit a small flat surface covered with grass; and if the atmosphere, during a calm and serene night, be admitted to be 10° warmer there than it is near the surface of the low grounds, which is a less difference than what sometimes occurs in such circumstances, it is manifest that, should both the grass upon the hill, and that upon the plain, acquire a cold of 10° by radiation, the former will, notwithstanding, be 10° warmer than the latter. Hence also the tops of trees are sometimes found dry when the grass on the ground’s surface has been found covered with dew.

1204. A very slight covering will exclude much cold. I had often, observes Dr. Wells, in the pride of half knowledge, smiled at the means frequently employed by gardeners, to protect tender plants from cold, as it appeared to me impossible, that a thin mat, or any such flimsy substance, could prevent them from attaining the temperature of the atmosphere, by which alone I thought them liable to be injured. But, when I had learned, that bodies on the surface of the earth become, during a still and serene night, colder than the atmosphere, by radiating their heat to the heavens, I perceived immediately a just reason for the practice, which I had before deemed useless. Being desirous, however, of acquiring some precise information on this subject, I fixed, perpendicularly, in the earth of a grass-plot, four small sticks, and over their upper extremities, which were six inches above the grass, and formed the corners of a square, the sides of which were two feet long, drew tightly a very thin cambric handkerchief. In this disposition of things, therefore, nothing existed to prevent the free passage of air from the exposed grass, to that which was sheltered, except the four small sticks, and there was no substance to radiate heat downwards to the latter grass, except the cambric handkerchief. The temperature of the grass, which was thus shielded from the sky, was, upon many nights afterwards examined by me, and was always found higher than that of neighbouring grass which was uncovered, if this was colder than the air. When the difference in temperature, between the air several feet above the ground and the unsheltered grass, did not exceed 5°, the sheltered grass was about as warm as the air. If that difference, however, exceeded 5°, the air was found to be somewhat warmer than the sheltered grass. Thus, upon one night, when fully exposed grass was 11° colder than the air, the latter was 3° warmer than the sheltered grass; and the same difference existed on another night, when the air was 14° warmer than the exposed grass. One reason for this difference, no doubt, was that the air, which passed from the exposed grass, by which it had been very much cooled, to that under the handkerchief, had deprived the latter of part of its heat; another, that the handkerchief, from being made colder than the atmosphere by the radiation of its upper surface to the heavens, would remit somewhat less heat to the grass beneath, than what it received from that substance. But still, as the sheltered grass, notwithstanding these drawbacks, was upon one night, as may be collected from the preceding relation, 8°, and upon another 11°, warmer than grass fully exposed to the sky, a sufficient reason was now obtained for the utility of a very slight shelter to plants, in averting or lessening injury from cold, on a still and serene night.

1205. The covering has most effect when placed at a little distance above the plants or objects to be sheltered. A difference in temperature, of some magnitude, was always observed on still and serene nights, between bodies sheltered from the sky by substances touching them, and similar bodies, which were sheltered by a substance a little above them. I found, for example, upon one night, that the warmth of grass, sheltered by a cambric handkerchief raised a few inches in the air, was 3° greater than that of a neighbouring piece of grass which was sheltered by a similar handkerchief actually in contact with it. On another night, the difference between the temperatures of two portions of grass, shielded in the same manner, as the two above mentioned, from the influence of the sky, was 4°. Possibly, continues Dr. Wells, experience has long ago taught gardeners the superior advantage of defending tender vegetables, from the cold of clear and calm nights, by means of substances not directly touching them; though I do not recollect ever having seen any contrivance for keeping mats, or such like bodies, at a distance from the plants which they were meant to protect.

1206. Heat produced by walls. Walls, Dr. Wells observes, as far as warmth is concerned, are regarded as useful, during a cold night, to the plants which touch them, or are near to them, only in two ways; first, by the mechanical shelter which they afford against cold winds, and secondly, by giving out the heat which they had acquired during the day. It appearing to me, however, that, on clear and calm nights, those on which plants frequently receive much injury from cold, walls must be beneficial in a third way, namely, by preventing, in part, the loss of heat, which the plants would sustain from radiation, if they were fully exposed to the sky: the following experiment was made for the purpose of determining the justness of this opinion. A cambric handkerchief having
been placed, by means of two upright sticks, perpendicularly to a grass-plot, and at right angles to the course of the air, a thermometer was laid upon the grass close to the lower edge of the handkerchief, on its windward side. The thermometer thus situated was several nights compared with another lying on the same grass-plot, but on a part of it fully exposed to the sky. On two of these nights, the air being clear and calm, the grass close to the handkerchief was found to be 4° warmer than the fully exposed grass. On a third, the difference was 6°. An analogous fact is mentioned by Gersten, who says, that a horizontal surface is more abundantly dewed, than one which is perpendicular to the ground.

1207. Heat from a covering of snow. The covering of snow, the same author observes, which countries in high latitudes enjoy during the winter, has been very commonly thought to be beneficial to vegetable substances on the surface of the earth, as far as their temperature is concerned, solely by protecting them from the cold of the atmosphere. But were this supposition just, the advantage of the covering would be greatly circumscribed; since the upper parts of trees and of tall shrubs are still exposed to the influence of the air. Another reason, however, is furnished for its usefulness, by what has been said in this essay; which is, that it prevents the occurrence of the cold, which bodies on the earth acquire, in addition to that of the atmosphere, by the radiation of their heat to the heavens during still and clear nights. The cause, indeed, of this additional cold, does not constantly operate; but its presence, during only a few hours, might effectually destroy plants, which now pass unhurt through the winter. Again, as things are, while low vegetable productions are prevented, by their covering of snow, from becoming colder than the atmosphere in consequence of their own radiation, the parts of trees and tall shrubs, which rise above the snow, are little affected by cold from this cause. For their outermost twigs, now that they are destitute of leaves, are much smaller than the thermometers suspended by me in the air, which in this situation very seldom became more than 2° colder than the atmosphere. The larger branches, too, which, if fully exposed to the sky, would become colder than the extreme parts, are, in a great degree, sheltered by them; and, in the last place, the trunks are sheltered both by the smaller and the larger parts, not to mention that the trunks must derive heat, by conduction through the roots, from the earth kept warm by the snow. In a similar way is partly to be explained the manner, in which a layer of earth or straw preserves vegetable matters in our own fields, from the injurious effects of cold in winter. (Essay on Dريع, & c. 1819.)

1208. The nature of light is totally unknown: the light which proceeds from the sun seems to be composed of three distinct substances. Scheel discovered that a glass mirror held before the fire reflected the rays of light, but not the rays of caloric; but when a metallic mirror was placed in the same situation, both heat and light were reflected. The mirror of glass became hot in a short time, but no change of temperature took place on the metallic mirror. This experiment shows that the glass mirror absorbed the rays of caloric, and reflected those of light; while the metallic mirror, suffering no change of temperature, reflected both. And if a plate glass be held before a burning body, the rays of light are not sensibly interrupted, but the rays of caloric are intercepted; for no sensible heat is observed on the opposite side of the glass; but when the glass has reached a proper degree of temperature, the rays of caloric are transmitted with the same facility as those of light. And thus the rays of light and caloric may be separated. But the curious experiments of Dr. Herschel have clearly proved that the invisible rays which are emitted by the sun, have the greatest heating power. In those experiments, the different colored rays were thrown on the bulb of a very delicate thermometer, and their heating power was observed. The heating power of the violet, green, and red rays were found to be each other as the following numbers: violet, 16.0; green, 22.4; red, 55.0. The heating power of the most refrangible rays was least, and this power increases as the refrangibility diminishes. The red ray, therefore, has the greatest heating power, and the violet, which is the most refrangible, the least. The illuminating power, it has been already observed, is greatest in the middle of the spectrum, and it diminishes towards both extremities; but the heating power, which is least at the violet end, increases from that to the red extremity; and when the thermometer was placed beyond the limit of the red ray, it rose still higher than in the red ray, which has the greatest heating power in the spectrum. The heating power of these invisible rays was greatest at the distance of half an inch beyond the red ray, but it was sensible at the distance of one inch and a half.

1209. The influence of the different solar rays on vegetation has not yet been studied; but it is certain that the rays exercise an influence independent of the heat they produce. Thus plants kept in darkness, but supplied with heat, air, and moisture, grow for a short time, but they never gain their natural colors; their leaves are white and pale, and their juices watery and peculiarly saccharine: according to Knight they merely
expend the sap previously generated under the influence of light. (Notes to Sir H. Davy's Agr. Chem. p. 402.)

Sect. II. Of Electricity.

1210. Electrical changes are constantly taking place in nature, on the surface of the earth, and in the atmosphere; but as yet the effects of this power in vegetation have not been correctly estimated. It has been shown by experiments made by means of the voltaic battery, that compound bodies in general, are capable of being decomposed by electrical powers, and it is probable that the various electrical phenomena occurring in our system, must influence both the germination of seeds and the growth of plants. It has been found that corn sprouted much more rapidly in water positively electrified by the voltaic instrument, than in water negatively electrified; and experiments made upon the atmosphere show that clouds are usually negative; and, as when a cloud is in one state of electricity, the surface of the earth beneath is brought into the opposite state, it is probable that in common cases the surface of the earth is positive. A similar experiment is related by Dr. Darwin. (Phytologia, sect. xiii. 2, 3.)

1211. Respecting the nature of electricity different opinions are entertained amongst scientific men; by some, the phenomena are conceived to depend upon a single subtle fluid, in excess in the bodies said to be positively electrified, and in deficiency in the bodies said to be negatively electrified. A second class suppose the effects to be produced by two different fluids, called by them the vitreous fluid and the resinous fluid; and others regard them as affections or motions of matter, or an exhibition of attractive powers, similar to those which produce chemical combination and decomposition; but usually exerting their action on masses.

1212. A profitable application of electricity, Dr. Darwin observes, to promote the growth of plants is not yet discovered; it is nevertheless probable, that in dry seasons, the erection of numerous metallic points on the surface of the ground, but a few feet high, might, in the night-time, contribute to precipitate the dew by facilitating the passage of electricity from the air into the earth; and that an erection of such points higher in the air by means of wires wrapped round tall rods, like angle rods, or elevated on buildings, might frequently precipitate showers from the higher parts of the atmosphere. Such points erected in gardens might promote a quicker vegetation of the plants in their vicinity, by supplying them more abundantly with the electric ether. (Phytologia, xiii. 4.) J. Williams (Climate of Great Britain, 348,) enlarging on this idea, proposes to erect large electrical machines, to be driven by wind, over the general face of the country, for the purpose of improving the climate, and especially for lessening that superabundant moisture which he contends is yearly increasing from the increased evaporating surface, produced by the vegetation of improved culture, and especially from the increase of pastures, hedges, and ornamental plantations.

Sect. III. Of Water.

1213. Water is a compound of oxygene and hydrogen gas, though primarily reckoned a simple or elementary substance. "If the metal called potassium be exposed in a glass tube to a small quantity of water, it will act upon it with great violence; elastic fluid will be disengaged, which will be found to be hydrogen; and the same effects will be produced upon the potassium, as if it had absorbed a small quantity of oxygen; and the hydrogen disengaged, and the oxygen added to the potassium, are in weight as 2 to 15; and if two in volume of hydrogen, and one in volume of oxygen, which have the weights of 2 and 15, be introduced into a close vessel, and an electrical spark passed through them, they will inflame and condense into 17 parts of pure water."  

1214. Water is absolutely necessary to the economy of vegetation in its elastic and fluid state; and it is not devoid of use even in its solid form. Snow and ice are bad conductors of heat; and when the ground is covered with snow, or the surface of the soil or of water is frozen, the roots or bulbs of the plants beneath are protected by the congealed water from the influence of the atmosphere, the temperature of which, in northern winters, is usually very much below the freezing point; and this water becomes the first nourishment of the plant in early spring. The expansion of water during its congelation, at which time its volume increases one twelfth, and its contraction of bulk during a thaw, tend to pulverise the soil, to separate its parts from each other, and to make it more permeable to the influence of the air.
SCIENCE OF GARDENING.

PART II.

CHAP. IV.

Of the Agency of the Atmosphere in Vegetation.

1215. The aerial medium which envelopes the earth may be studied chemically and physically; the first study respects the elements of which the atmosphere is composed; and the second their action in a state of combination, and as influenced by various causes, or those phenomena which constitute the weather.

SECT. I. Of the Elements of the Atmosphere.

1216. Water, carbonic acid gas, oxygen, and azote, are the principal substances composing the atmosphere; but more minute enquiries respecting their nature and agencies are necessary to afford correct views of its uses in vegetation.

1217. That water exists in the atmosphere is easily proved. If some of the salt, called muriate of lime, that has been just heated red, be exposed to the air, even in the driest and coldest weather, it will increase in weight, and become moist; and in a certain time will be converted into a fluid. If put into a retort and heated, it will yield pure water; will gradually recover its pristine state; and, if heated red, its former weight: so that it is evident that the water united to it was derived from the air. And that it existed in the air in an invisible and elastic form, is proved by the circumstance, that if a given quantity of air be exposed to the salt, its volume and weight will diminish, provided the experiment be correctly made.

1218. The quantity of water which exists in air, as vapor, varies with the temperature. In proportion as the weather is hotter, the quantity is greater. At 50° of Fahrenheit, air contains about one 50th of its volume of vapor; and as the specific gravity of vapor is to that of air nearly as 10 to 16; this is about one 75th of its weight. At 100°, supposing that there is a free communication with water, it contains about one 14th part in volume, or one 21st in weight. It is the condensation of vapor by diminution of the temperature of the atmosphere, which is probably the principal cause of the formation of clouds, and of the deposition of dew, mist, snow, or hail.

1219. The power of different substances to absorb aqueous vapor from the atmosphere by cohesive attraction has been already referred to. (1058.) The leaves of living plants appear to act upon this vapor in its elastic form, and to absorb it. Some vegetables increase in weight from this cause, when suspended in the atmosphere and unconnected with the soil; such as the house-leek, and different species of the aloe. In very intense heats, and when the soil is dry, the life of plants seems to be preserved by the absorbent power of their leaves; and it is a beautiful circumstance in the economy of nature, that aqueous vapor is most abundant in the atmosphere when it is most needed for the purposes of life; and that when other sources of its supply are cut off, this is most copious.

1220. The existence of carbonic acid gas in the atmosphere is proved by the following process: if a solution of lime and water be exposed to the air, a pellicle will speedily form upon it, and a solid matter will gradually fall to the bottom of the water, and in a certain time the water will become tasteless; this is owing to the combination of the lime which was dissolved in the water with carbonic acid gas, which existed in the atmosphere, as may be proved by collecting the film and the solid matter, and igniting them strongly in a little tube of platina or iron; they will give out carbonic acid gas, and will become quick-lime, which, added to the same water, will again bring it to the state of lime-water.

1221. The quantity of carbonic acid gas in the atmosphere is very small. It is not easy to determine it with precision, and it must differ in different situations; but where there is a free circulation of air, it is probably never more than one 500th, nor less than one 800th of the volume of air. Carbonic acid gas is nearly one third heavier than the other elastic parts of the atmosphere in their mixed state; hence at first view it might be supposed that it would be most abundant in the lower regions of the atmosphere; but unless it has been immediately produced at the surface of the earth in some chemical process, this does not seem to be the case; elastic fluids of different specific gravities have a tendency to equable mixture by a species of attraction, and the different parts of the atmosphere are constantly agitated and blended together by winds or other causes. De Saussure found lime-water precipitated on Mount Blanc, the highest point of land in Europe; and carbonic acid gas has been always found, apparently in due proportion, in the air brought down from great heights in the atmosphere by aerostatic adventurers.

1222. The principal consumption of the carbonic acid in the atmosphere seems to be in affording nourishment to plants; and some of them appear to be supplied with carbon chiefly from this source.

1223. The formation of carbonic acid gas takes place during fermentation, combustion, putrefaction, respiration, and a number of operations taking place upon the surface of the
earth; and there is no other process known in nature by which it can be destroyed but by vegetation.

1224. Oxygen and azote are the remaining constituents of the atmosphere. After a given portion of common air has been deprived of aqueous vapor and carbonic acid gas, it appears little altered in its properties; it remains a compound of oxygen and azote, which supports combustion and animal life. There are many modes of separating these two gases from each other. A simple one is by burning phosphorus in a confined volume of air: this absorbs the oxygen and leaves the azote; and 100 parts in volume of air, in which phosphorus has been burnt, yield 79 parts of azote; and by mixing this azote with 21 parts of fresh oxygen gas artificially procured, a substance having the original characters of air is produced. To procure pure oxygen from air, quicksilver may be kept heated in it, at about 600°, till it becomes a red powder; this powder, when ignited, will be restored to the state of quicksilver by giving off oxygen.

1225. Oxygen is necessary to some functions of vegetables; but its great importance in nature is in its relation to the economy of animals. It is absolutely necessary to their life. Atmospheric air taken into the lungs of animals, or passed in solution in water through the gills of fishes, loses oxygen; and for the oxygen lost, about an equal volume of carbonic acid appears.

1226. The effects of azote in vegetation are not distinctly known. As it is found in some of the products of vegetation, it may be absorbed by certain plants from the atmosphere. It prevents the action of oxygen from being too energetic, and serves as a medium in which the more essential parts of the air act; nor is this circumstance unconditionally to the analogy of nature; for the elements most abundant on the solid surface of the globe, are not those which are the most essential to the existence of the living beings belonging to it.

1227. The action of the atmosphere on plants differs at different periods of their growth, and varies with the various stages of the development and decay of their organs. We have seen (728) that if a healthy seed be moistened and exposed to air at a temperature not below 45°, it soon germinates, and shoots forth a plume, which rises upwards, and a radicle which descends. If the air be confined, it is found that in the process of germination the oxygen, or a part of it, is absorbed. The azote remains unaltered; no carbonic acid is taken away from the air; on the contrary, some is added. Seeds are incapable of germinating, except when oxygen is present. In the exhausted receiver of the air-pump, in pure azote, or in pure carbonic acid, when moistened they swell, but do not vegetate; and if kept in these gases, lose their living powers, and undergo putrefaction. If a seed be examined before germination, it will be found more or less insipid, at least not sweet; but after germination it is always sweet. Its coagulated mucilage, or starch, is converted into sugar in the process; a substance difficult of solution is changed into one easily soluble; and the sugar carried through the cells or vessels of the cotyledons, is the nourishment of the infant plant. The absorption of oxygen by the seed in germination, has been compared to its absorption in producing the evolution of vital life in the egg; but this analogy is only remote. All animals, from the most to the least perfect classes, require a supply of oxygen. From the moment the heart begins to pulsate till it ceases to beat, the aeration of the blood is constant, and the function of respiration invariable; carbonic acid is given off in the process, but the chemical change produced in the blood is unknown; nor is there any reason to suppose the formation of any substance similar to sugar. It is evident, that in all cases of semination, the seeds should be sown so as to be fully exposed to the influence of the air. And one cause of the unproductiveness of cold cleyey adhesive soils is, that the seed is coated with matter impermeable to air. In sandy soils the earth is always sufficiently penetrable by the atmosphere; but in cleyey soils there can scarcely be too great a mechanical division of parts. Any seed not fully supplied with air, always produces a weak and diseased plant. We have already seen (756) that carbon is added to plants from the air by the process of vegetation in sunshine; and oxygen is added to the atmosphere at the same time.

1228. Those changes in the atmosphere which constitute the most important meteorological phenomena, may be classed under five distinct heads; the alterations that occur in the weight of the atmosphere; those that take place in its temperature; the changes produced in its quantity by evaporation and rain; the excessive agitation to which it is frequently subject; and the phenomena arising from electric and other causes, that at particular times occasion or attend the precipitations and agitations alluded to. All the above phenomena prove to demonstration that constant changes take place, the consequences of new combinations and decompositions rapidly following each other.

1229. With respect to the changes in the weight of the atmosphere it is generally known that the instrument called the barometer shows the weight of a body of air immediately above it, extending to the extreme boundary of the atmosphere, and the base of which is equal to that of the mercury contained within it. As the level of the sea is the lowest
point of observation, the column of air over a barometer placed at that level is the longest to be obtained.

The variations of the barometer between the tropics are very trifling, and it does not descend more than half as much in that part of the globe at every two hundred feet of elevation as it does beyond the tropics. The range of the barometer increases gradually as the latitude increases toward the poles; and in the end it amounts to two or three inches. The following Table will explain this gradual increase:

The range of the barometer is considerably less in North America than in the corresponding latitudes of Europe, particularly in Virginia, where it never exceeds 11. The range is more considerable at the level of the sea than at the higher elevations; and in the same degree of latitude it is in the inverse ratio of the height of the place above the level of the sea. Cotte composed a table, which has been published in the Journal de Physique, from which it appears extremely probable, that the barometer has an invariable tendency to rise between the morning and the evening, and that this impulse is most considerable from two in the afternoon till nine at night, when the greatest elevation is produced; but the elevation at nine differs from that at two by four twelfths, while that of two varies from the elevation of the morning only by one twelfth, and that in particular climates the greatest elevation is at two o'clock. The observations of Luke Howard; and from them it is concluded, that the barometer is influenced by some depressing cause at new and full moon, and that some other makes it rise at the quarters. This coincidence is most considerable in fair and calm weather; the depression in the interval between the quarters and conjunctions amounts to one tenth of an inch, and the rise from the conjunctions to the quarters is to the same amount. The range of this instrument is found to be greater in winter than in summer; for instance, the mean at York, during the months from October to March inclusive, in the year 1725, was 142, and in the six succeeding months 1016.

The more serene and settled the weather, the higher the barometer ranges; calm weather, with a tendency to rain, depresses it; high winds have a similar effect on it; and the greatest elevation occurs with easterly and northerly winds; but the south produces a directly contrary effect.

1290. The variations in the temperature of the air in any particular place, exclusive of the differences of seasons and climates, are very considerable. These changes cannot be produced by heat derived from the sun, as its rays concentrated have no kind of effect on air; those, however, heat the surface of our globe, which is communicated to the immediate atmosphere; it is through this fact that the temperature is highest where the place is so situated as to receive with most effect the rays of the sun, and that it varies in each region with the season; it is also the cause why it decreases in proportion to the height of the air above the surface of the earth. The most perpendicular rays falling on the globe at the equator, there the heat of it is the greatest, and that heat decreases gradually to the poles, of course the temperature of the air is in exact unison; from this, it appears, that the air acquires the greatest degree of warmth over the equator, where it becomes insensibly cooler till we arrive at the poles; in the same manner, the air immediately above the equator cools gradually. Though the temperature sinks as it approaches the pole, and is highest at the equator, yet as it varies continually with the seasons, it is impossible to form an accurate idea of the progression without forming a mean temperature for a year, from that of the temperature of every degree of latitude for every day of the year, which may be accomplished by adding together the whole of the observations and dividing by their number, when the quotient will be the mean temperature for the year. The diminution," says Dr. Thomson, "from the pole to the equator takes place in a mathematical progression; or to speak more properly, the annual temperature of all the latitudes, are arithmetical means between the mean annual temperature of the equator and the pole. And as far as heat depends in the action of solar rays, that of each month is as the mean altitude of the sun, or rather as the sine of the sun's altitude."

1231. Inconsiderable seas, in temperate and cold climates, are colder in winter and warmer in summer than the main ocean, as they are necessarily under the influence of natural operations from the land. Thus the Gulf of Bothnia, is generally frozen in winter, but the water is sometimes heated in the summer to 70°, a state, the opposite part of the Atlantic never acquires; the German Sea is five degrees warmer in summer than the Atlantic, and more than three colder in winter; the Mediterranean is almost throughout warmer both in winter and summer, which therefore causes the Atlantic to flow into it; and the Black Sea being colder than the Mediterranean, flows into the latter.

The eastern parts of North America, as appears from meteorological tables, have a much colder air than the opposite European coast, and fall short of the standard by about ten or twelve degrees. There are several causes which produce this considerable difference. The nearest part of the Northern ocean, between the 40th and 50th degree of north latitude, and the 100th and 110th of longitude west from London; and there the most considerable rivers have their origin. The height alone is sufficient to make this tract colder than it would otherwise be; but there are other causes, and these are most extensive forests, and large swamps and morasses, each of which exclude heat from the earth, and consequently prevent it from illuminating the rigor of winter. Many extensive lakes lie to the east, and Hudson's Bay more to the north; a chain of mountains extends on the south of the latter, and those equally prevent the accumulation of heat; besides, this bay is bounded on the east by the mountainous country of Labrador, and has many islands; from all which circumstances arise the lowness of the temperature, and the piercing cold of the north-west winds. The annual decrease of the forests for the purpose of clearing the ground
and the consumption for building and fuel, is supposed to have occasioned a considerable decrease of cold in the winter; and if this should be the result, much will yet be due towards bringing the temperature of the European and American continents to something like a level.

1292. Continents have a colder atmosphere than islands situated in the same degree of latitude; and countries lying to the windward of the superior classes of mountains, or forests, are warmer than those which are to the leeward. Earth always possessing a certain degree of moisture, has a greater capacity to receive and retain heat than sand or stones, the latter therefore are heated and cooled with more rapidity: it is from this circumstance that the intense heats of Africa and Arabia, and the cold of Terra del Fuego, are derived. The temperature of growing vegetables changes very gradually; but there is a considerable evaporation from them: if those exist in great numbers, and congregated, or in forests, their foliage preventing the rays of the sun from reaching the earth, it is perfectly natural that the immediate atmosphere must be greatly affected by the ascent of chilled vapors.

1293. Our next object is the ascent and descent of water: the principal appearances of this element are vapor, clouds, dew, rain, frost, hail, snow, and ice.

1294. Vapor is water rarefied by heat, in consequence of which becoming lighter than the atmosphere, it is raised considerably above the surface of the earth, and afterwards by a partial condensation forms clouds. It differs from exhalation, which is properly a dispersion of dry particles from a body. When water is heated to 212° it boils, and is rapidly converted into steam; and the same change takes place in much lower temperatures; but in that case the evaporation is slower, and the elasticity of the steam is smaller. As a very considerable proportion of the earth’s surface is covered with water, and as this water is constantly evaporating and mixing with the atmosphere in the state of vapor, a precise determination of the rate of evaporation must be of very great importance in meteorology. Evaporation is confined entirely to the surface of the water; hence it is, in all cases, proportional to the surface of the water exposed to the atmosphere. Much more vapor of course rises in maritime countries or those interspersed with lakes, than in inland countries. Much more vapor rises during hot weather than during cold: hence the quantity evaporated depends in some measure upon temperature. The quantity of vapor which rises from water, even when the temperature is the same, varies according to circumstances. It is least of all in calm weather, greater when a breeze blows, and greatest of all with a strong wind. From experiments, it appears, that the quantity of vapor raised annually at Manchester is equal to about 25 inches of rain. If to this we add five inches for the dew, with Dalton, it will make the annual evaporation 30 inches. Now, if we consider the situation of England, and the greater quantity of vapor raised from water, it will not surely be considered as too great an allowance, if we estimate the mean annual evaporation over the whole surface of the globe at 35 inches.

1295. A cloud is a mass of vapor, more or less opaque, formed and sustained at considerable height in the atmosphere, probably by the joint agencies of heat and electricity. The first successful attempt to arrange the diversified form of clouds, under a few general modifications, was made by Luke Howard, Esq. We shall give here a brief account of his ingenious classification.

1296. The simple modifications are thus named and defined:—1. Cirrus, parallel, flexuous, or diverging fibres, extensible in any or in all directions (fig. 75. a); 2. Cumulus, convex or conical heaps, increasing upwards from a horizontal base (d); 3. Stratus, a widely-extended, continuous, horizontal sheet, increasing from below (c).

1297. The intermediate modifications which require to be noticed are, 4. Cirro-cumulus, small, well-defined, roundish masses, in close horizontal arrangement (d); 5. Cirro-stratus, horizontal or slightly inclined masses, attenuated towards a part or the whole of their circumference, bent downward or undulated, separate or in groups consisting of small clouds having these characters (e).

1298. The compound modifications are, 6. Cumulo-stratus, or twin cloud; the cirro-stratus, blended with the cumulus, and either appearing intermixed with the heaps of the latter, or superadding a wide-spread structure to its base (f); 7. Cumulo-cirro-stratus, vel Nimbus; the rain-cloud, a cloud or system of clouds from which rain is falling. It is a horizontal sheet, above which the cirrus spreads, while the cumulus enters it laterally and from beneath (g, g); 8. The Fall Cloud, resting apparently on the surface of the ground (h).

1299. The cirrus appears to have the least density, the greatest elevation, the greatest variety of extent and direction, and to appear earliest in serene weather, being indicated by a few threads pencilled on the sky. Before storms they appear lower and denser, and usually in the quarter opposite to that from which the storm arises. Steady high winds are also preceded and attended by cirrus streaks, running quite across the sky in the direction they blow in.

1300. The cumulus has the densest structure, is formed in the lower atmosphere, and moves along with the current next the earth. A small irregular spot first appears, and it, as it were, the nucleus on which they increase. The lower surface continues irregularly plane, while the upper rises into conical or hemispherical heaps; which may afterwards continue long nearly of the same bulk, or rapidly rise into moun-
tains. They will begin, in fair weather, to form some hours after sunrise, arrive at their maximum in the hottest part of the afternoon, then go on diminishing, and totally disperse about sunset. Previous to rain the cumulus increases rapidly, appears lower in the atmosphere, and with its surface full of loose fleeces or protuberances. The formation of large cumuli to leeward in a strong wind, indicates the approach of a calm with rain. When they do not disappear or subside about sunset, but continue to rise, thunder is to be expected in the night.

1241. The stratus has a mean degree of density, and is the lowest of clouds, its inferior surface commonly resting on the earth in water. This is properly the cloud of night, appearing about sunset. It comprehends all those creeping mists which in calm weather ascend in spreading sheets (like an inundation of water) from the bottoms of valleys, and the surfaces of lakes and rivers. On the return of the sun, the level surface of this cloud begins to put on the appearance of cumulus, the whole at the same time separating from the ground. The continuity is next destroyed, and the cloud ascends and evaporates, or passes off with the appearance of the nascent cumulus. This has long been experienced as a prognostic of fair weather.

1242. Transition of forms. The cirrus having continued for sometime increasing or stationary, usually passes either to the cirro-cumulus or the cirro-stratus, at the same time descending to a lower station in the atmosphere. This modification forms a very beautiful sky, and is frequently in summer an attendant on warm and dry weather. The cirro-stratus, when seen in the distance, frequently gives the idea of shoals of fish. It precedes wind and rain; is seen in the intervals of storms; and sometimes alternates with the cirro-cumulus in the same cloud, when the different evolutions form a curious spectacle. A judgment may be formed of the weather likely to ensue by observing which modification prevails at last. The solar and lunar halos, as well as the parhelion and paraselene (mock sun and mock moon), prognostics of foul weather, are occasioned by this cloud. The cumulo-stratus precedes, and the nimbus accompanies rain.

1243. Dew is the moisture insensibly deposited from the atmosphere on the surface of
the earth. This moisture is precipitated by the cold of the body on which it appears, and will be more or less abundant, not in proportion to the coldness of that body, but in proportion to the existing state of the air in regard to moisture. It is commonly supposed that the formation of dew produces cold, but like every other precipitation of water from the atmosphere, it must evidently produce heat.

1848. Phenomena of dew. Aristotle justly remarked, that dew appears only on calm and clear nights. Dr. Wells shows, that very little is ever deposited in opposite circumstances; and that little only when the clouds are very high. It is never seen on nights both cloudy and windy; and if in the course of the night the weather, from being serene, should become sport and wind had been blowing, then before sunrise, the sky would be perfectly covered with clouds, more dew will appear than if it were entirely uncovered. Dew probably begins in the country to appear upon grass in places shaded from the sun, during clear and calm weather, soon after the heat of the atmosphere has declined, and continues to be deposited throughout the night for a considerable time. Its quantity will depend in some measure on the opposition of moisture in the atmosphere, and is consequently greater after rain than after a long tract of dry weather; and in Europe, with southerly and westerly winds, than with those which blow from the north and the east. The direction of the sea determines this relation of the winds to the dew. For instance, dew falls very much less in the distance of the winds to the sea.

1246. Rain. Luke Howard, who may be considered as our most accurate scientific meteorologist, is inclined to think, that rain is in almost every instance the result of the electrical action of clouds upon each other.

1847. Phenomena of rain. Rain never descends till the transparency of the air ceases, and the invisible vapors become visible, when clouds form, and at length the drops fall; clouds, instead of forming gradually at once throughout all parts of the horizon, generate in a particular spot, and imperceptibly increase till the whole expanse is obscured.

1248. The cause of rain is thus accounted for by Dalton. If two masses of air, of unequal temperatures, by the ordinary currents of the winds, are intermixed, when saturated with vapor, a precipitation ensues. If the masses are under saturation, then less precipitation takes place, or none at all, according to the degree. Also the warmer the air, the greater is the quantity of vapor precipitated in like circumstances. Hence the reason why rains are heavier in summer than in winter, and in warm countries than in cold.

1249. The quantity of rain, taken at an annual mean, is the greatest at the equator, and it lessens gradually to the poles; but there are fewer days of rain there, the number of which increase in proportion to the distance from it. From north latitude 12° to 43° the mean number of rainy days is 78; from 43° to 46° the mean number is 103; from 46° to 50°, 134; and from 51° to 60°, 161. Winter often produces a greater number of rainy days than summer, though the quantity of rain is more considerable in the latter than in the former season; at Petersburg rain and snow falls on an average 84 days of the winter, and the quantity amounts to about five inches; on the contrary the summer produces eleven inches in about the same number of days. Mountainous districts are subject to great falls of rain; among the Andes particularly it rains almost incessantly, while the flat country of Egypt is consumed by endless drought. Dalton estimates the quantity of rain falling in England at 31 inches. The mean annual quantity of rain for the whole globe is 34 inches.

1250. The cause why less rain falls in the first six months of the year than in the last six months is thus explained. The whole quantity of water in the atmosphere in January is usually about three inches, as appears from the dew point, which is then about 32°.
Now the force of vapors at that temperature is 0·2 of an inch of mercury, which is equal to 2·8 or three inches of water. The dew point in July is usually about 58° or 59°, corresponding to 0·5 of an inch of mercury, which is equal to seven inches of water; the difference is four inches of water, which the atmosphere then contains more than in the former month. Hence, supposing the usual intermittence of currents of air in both the intervening periods to be the same, the rain ought to be four inches less in the former period of the year than the average, and four inches more in the latter period, making a difference of eight inches between the two periods, which nearly accords with the preceding observations.

1251. The mean monthly and annual quantities of rain at various places, deduced from the average for many years, by Dalton, is given in the following Table:

1252. Frost, being derived from the atmosphere, naturally proceeds from the upper parts of bodies downwards, as the water and the earth; so the longer a frost is continued, the thicker the ice becomes upon the water in ponds, and the deeper into the earth the ground is frozen. In about 16 or 17 days' frost, Boyle found it penetrated 14 inches into the ground. At Moscow, in a hard season, the frost will penetrate two feet deep into the ground; and Captain James found it penetrated 10 feet deep in Charlton island, and the water in the same island was frozen to the depth of six feet. Scheffer assures us, that in Sweden the frost pieces two cubits (a Swedish cull), into the earth, and turns what moisture is found there into a whitish substance, like ice; and standing water to three ells or more. The same author also mentions sudden cracks or rifts in the ice of the lakes of Sweden, nine or ten feet deep, and many leagues long; the rupture being made with a noise not less loud than if many guns were discharged together. By such means however the fishes are furnished with air, so that they are rarely found dead.

The history of frosts furnishes very extraordinary facts. The trees are often scorched and burnt up, as with the most excessive heat, in consequence of the separation of water from the air, which is therefore very drying. In the great frost in 1685, the trunks of oak, ash, walnut, and other trees were miserably split and cleft, so that they might be seen through, and the cracks often attended with dreadful noises like the explosion of fire-arms.

1253. Hail is generally defined as frozen rain, it differs from it in that the hailstones are not formed of single pieces of ice, but of many little spherules agglutinated together; neither are those spherules all of the same consistence; some of them being hard and solid, like perfect ice; others soft, and mostly like snow hardened by a severe frost. Hailstone has a kind of core of this soft matter; but more frequently the core is solid and hard, while the outside is formed of a softer matter. Hailstones assume various figures, being sometimes round, at other times pyramidal, crenated, angular, thin, and flat, and sometimes stellated with six radii, like the small crystals of snow. Natural historians furnish us with various accounts of surprising showers of hail in which the hailstones were of extraordinary magnitude.

1254. Snow is formed by the freezing of the vapors in the atmosphere. It differs from hail and hoar frost, in being as it were crystallised, which they are not. As the flakes fall down through the atmosphere, they are continually joined by more of these radiated spicula, and they increase in bulk like the drops of rain or hailstones. The lightness of snow, although it is firm ice, is owing to the excess of its surface in comparison to the matter contained under it: as gold itself may be extended in surface till it will ride upon the least breath of air. The whiteness of snow is owing to the small particles into which it is divided; for ice when pounded, will become equally white.

1255. Snow is of great use to the vegetable kingdom. Were we to judge from appearance only, we might imagine, that so far from being useful to the earth, the cold humidity of snow would be detrimental to vegetation. But the experience of all ages asserts the con-
trary. Snow, particularly in those northern regions where the ground is covered with it for several months, fructifies the earth, by guarding the corn or other vegetables from the intense cold of the air, and especially from the cold piercing winds. It has been a vulgar opinion, very generally received, that snow fertilises the land on which it falls more than rain, in consequence of the nitrous salts, which it is supposed to acquire by freezing. But it appears from the experiments of Margraaf, in the year 1731, that the chemical difference between rain and snow water, is exceedingly small; that the latter contains a somewhat less proportion of earth than the former; but neither of them contain either earth, or any kind of salt, in any quantity which can be sensibly efficacious in promoting vegetation. The peculiar agency of snow, as a fertiliser in preference to rain may be ascribed to its furnishing a covering to the roots of vegetables, by which they are guarded from the influence of the atmospheric cold, and the internal heat of the earth is prevented from escaping. The internal parts of the earth are heated uniformly to the fifty-eighth degree of Fahrenheit's thermometer. This degree of heat is greater than that in which the watery juices of vegetables freeze, and it is propagated from the inward parts of the earth to the surface, on which the vegetables grow. The atmosphere, being variably heated by the action of the sun in different climates, and in the same climate at different seasons, communicates to the surface of the earth, and to some distance below it, the degree of heat or cold which prevails in itself. Different vegetables are able to preserve life under different degrees of cold, but all of them perish when the cold which reaches their roots is extreme. Providence has, therefore, in the coldest climates, provided a covering of snow for the roots of vegetables, by which they are protected from the influence of the atmospheric cold. The snow keeps in the internal heat of the earth, which surrounds the roots of vegetables, and defends them from the cold of the atmosphere.

1256. Ice is water in the solid state, during which the temperature remains constant, being 32 degrees of the scale of Fahrenheit. Ice is considerably lighter than water; namely, about one eighth part; and this increase of dimensions is acquired with prodigious force, sufficient to burst the strongest iron vessels, and even pieces of artillery. Congelation takes place much more suddenly than the opposite process of liquefaction; and, of course, the same quantity of heat must be more rapidly extricated in freezing, than it is absorbed in thawing; the heat thus extricated being disposed to fly off in all directions, and little of it being retained by the neighboring bodies, more heat is lost than is gained by the alternation: so that where ice has once been formed, its production is in this manner redoubled.

1257. The northern ice extends about 9° from the pole; the southern 18° or 20°; in some parts even 30°; and floating ice has occasionally been found in both hemispheres as far as 40° from the poles, and sometimes, as it has been said, even in latitude 41° or 42°. Between 54° and 60° south latitude, the snow lies on the ground, at the sea-side, throughout the summer. The line of perpetual congelation is three miles above the surface at the equator, where the mean heat is 84°; at Teneriffe, in latitude 28°, two miles; in the latitude of London, a little more than a mile; and in latitude 80° north, only 1250 feet. At the pole, according to the analogy deduced by Kirwan, from a comparison of various observations, the mean temperature should be 31°. In London the mean temperature is 50°; at Rome and at Montpelier, a little more than 60°; in the island of Madeira, 70°; and in Jamaica, 80°.

1258. Wind. Were it not for this agitation of the air, putrid effluvia arising from the habitations of man, and from vegetable substances, besides the exhalations from water, would soon render it unfit for respiration, and a general mortality would be the consequence. The prevailing winds of our own country, which were ascertained by order of the Royal Society of London, at London are,

The south wind blows more upon an average in each month of the year than any other, particularly in July and August; the north-east prevails during January, March, April, May, and June, and is most unfrequent in February, July, September, and December; the north-west occurring more frequently from November to March, and less so in September and October than in any other months.

Near Glasgow, the average is stated as follows:

In Ireland, the prevailing winds are the west and south-west.

1259. The different degrees of motion of wind next excites our attention; and it seems al-
most superfluous to observe, that it varies in gradations from the gentlest zephyr, which plays upon the leaves of plants, greatly undulating them, to the furious tempest, calculated to inspire horror in the breast of the most callous. It is also a remarkable fact, that violent currents of air pass along, as it were, within a line, without sensibly agitating that beyond them. An instance of this kind occurred at Edinburgh, where the celebrated aeronaut Lunardi ascended in his balloon, which was conveyed with great velocity by the wind at the rate of 70 miles an hour, while a perfect calm existed in the city and neighborhood.

1290. Causes of wind. There are many circumstances attending the operations of the air, which we term wind, that serve for a basis for well-founded conjectures, and those, united to the result of daily observation, render the explanation of its phenomena tolerably satisfactory. It must be clear to the most common caprice of the mind, that the phenomena of the earth and the torrid zone that part of it must receive a greater proportion of heat than those parts where they fall obliquely; the heat thus acquired communicates to the air, which it rarefies, and causes to ascend, and the vacuum occasioned by this operation is immediately filled by the air at the north and by the poles from the equator: at that point it moves at the rate of fifteen geographical miles in a minute in the same degree; therefore, if part of it was conveyed instantaneously from latitude 30°, it would not directly acquire the velocity of that at the equator. Consequently, though the velocity and pressure are similar upon the cold air proceeding from the north and south, this similarity must be admitted to extend to each particular place by the beams of the sun. The moon, being a large body situated comparatively near the earth, is known to affect the atmosphere in its respiration; it can, therefore, be doubted, that some of the winds we experience are caused by her motion.

1261. The regular motion of the atmosphere, known by the name of land and sea breezes, may be accounted for upon the above principle: the heated rarefied land air rises, and its place is supplied by the chill damp air of the hills in the neighborhood, becoming cold and dense in the air of the sea; the surface of the sea, the coast winds, the hills of the night, descends and presses upon the comparatively lighter air over the sea, and hence the land breeze. Granting that the attraction of the moon, and the diurnal movement of the sun affects our atmosphere, there cannot be a doubt but the motion of the heavenly bodies towards the earth, the consequence of which is an easterly current on each side: from this, it proceeds that south-west winds are so frequent in the western parts of Europe, and over the Atlantic Ocean. Kirwan attributes our constant south-west winds, particularly during winter, to an opposite current prevailing between the Atlantic and the Mediterranean. The same opinion the winds may be referred to in turn from the countries to the south of it, in the western parts of our hemisphere.

1262. The variable winds cannot be so readily accounted for; yet it is evident, that though they seem the effect of capricious causes, they depend upon a regular system, arranged by the great Author of nature. That accurate and successful observer of part of his works, the celebrated Franklin, discovered in 1740, that winds originate at the precise points towards which they blow. This philosopher had observed an eclipse of the moon at Philadelphia, on the 23rd of August, 1728, which prevented, by a mysterious operation, the heaviest wind which had for some time prevailed there. He afterwards found the winds to have been at the northern part of the United States, while the winter season was the north-east; in the spring, south-west, and in the summer, south-east. He then supposed the air to be created at the end of a gate. The water is at rest till the gate is opened; then it begins to move out through the gate, and the water next the gate is put in motion and moves towards the gate; and so on successively, till the water at the head of the canal is in motion, which is last of all. In this case all the water moves the same way: as to the air, that it will be caused by the various states of the atmosphere, and the sun, which is the cause of all the phenomena.

1263. Other descriptions of winds may arise from a variety of causes. As the atmosphere has been accustomed to be composed of air, vapor, and carbonic acid and water, it is well known these frequently change their aerial form, and combine with different substances, and the reverse; consequently partial winds and accumulations must continually occur, which occasion winds of different degrees of violence, continuance, and direction.

1264. The principal electrical phenomena of the atmosphere are thunder and lightning.

1265. Thunder is the noise occasioned by the explosion of a flash of lightning passing through the air: or it is that noise which is excited by a sudden explosion of electrical clouds, which are therefore called thunder-clouds.

The rattling, in the noise of thunder, which makes it seem as if it passed through arches, is probably owing to the sound being excited among clouds hanging over one another, and the agitated air passing irregularly between them.

The explosion, if high in the air and remote from us, will do no mischief; but when near, it may, and has, in a thousand instances, destroyed trees, animals, &c. This proximity, or small distance, may be estimated nearly by the interval of time between seeing the flash of lightning and hearing the report of the thunder, estimating the distance of the latter at the rate of 142 feet for a second of time, or 56 seconds of time, or 3 seconds of time, or about twenty seconds of time, which at the rate above-mentioned, gives the distance almost two miles. But sometimes it comes in a second or two, which argues the explosion very near to us, and even among us. And in such cases, the Doctor assures us, he has sometimes found both the motions of the ground happened. Although in this country thunder may happen at any time of the year, yet the months of July and August are those in which it may almost certainly be expected. Its devastation is of very uncertain continuance; sometimes only a few peals will be heard at any particular place during the whole month, and others not once or twice times in a year. The duration, as the intensity, is subject to a great variety: sometimes there are singular long periods, of a week, or a month, or more; other times, of six weeks, or even longer; not that we have violent thunder in this country directly vertical in any one place so frequently in any year, but in many seasons it will be perceptible that thunder-clouds are formed in the neighbourhood, even at these short intervals. Hence it is evident, both from the frequency of the phenomena, and the length of time they last, that if the mere effect of the weather, for we have often a long truce of hot weather

262 SCIENCE OF GARDENING. PART II.
Book II.  
OF THE ATMOSPHERE.

263.  Without any thunder; and besides, though not common, thunder is sometimes heard in the winter also. As therefore the heat of the weather is common to the whole summer, and, we must look for the causes of it in those phenomena, whatever they are, which are peculiar to the months of July, August, and the beginning of September. Now it is generally observed, that from the month of May to the end of June, the east wind prevails, for sometime wind, scarce, and continues with little interruption till towards the end of June. At that time, sometime sooner and sometimes later, a west wind takes its place, as the causes producing the east wind are not removed, the latter opposes the west wind with its whole force. At the place of meeting, there is naturally a most vehement pressure of the atmosphere, and friction of its particles against each other, and the violent heat, both from the atmosphere and from the earth, forming dark clouds, which can have little motion either way, because they are pressed almost equally on all sides. For the most part, however, the west wind prevails, and what little motion the clouds have is thrown towards the east: whence the common remark in this country, that "thunder-clouds move against the wind."

But this is by no means universal. For if the east wind does happen to be temporary before its natural period when it should take place, the east wind will very frequently get the better of it; and the clouds, even although thunder is produced, will move westward. Yet in either case, the reason is so obvious, that the most superficial observers cannot help taking notice of a considerable resistance in the atmosphere.

266.  Thunderbolts. When lightning acts with extraordinary violence, and breaks or shatters anything it is called a thunderbolt, which the vulgar, to fit it for such effects, suppose to be a hard body, and to be sent down to the earth from the sky. Beccaria, however, has said that we know nothing of a solid body of anything, more universally and commonly attributed to the thunderbolt, will be evident to any one, who considers those of gunpowder, and the several chemical fulminating powders, but more especially the astonishing powers of electricity, which are most visibly seen and employed by human art, and much more when directed and exercised in the course of nature. When we consider the known effects of electrical explosions, and those produced by lightning, we shall be at no loss to account for the extraordinary operations vulgarly ascribed to thunderbolts. As stones and bricks struck by lightning are often found in a vitrified state, we may reasonably suppose, with Beccaria, that some stones in the earth, having been struck in this manner, gave occasion to the vulgar opinion of the thunderbolt.

267.  Thunder-clouds are those clouds which are in a state fit for producing lightning and thunder. The first appearance of a thunder-storm, which usually happens when there is little or no wind, is one dense cloud, rising, and increasing very fast, as a thick smoke. The lower part of this cloud is black, and nearly level; but the upper finely arched, and well defined. Many of these clouds often seem piled upon one another, all arched in the same manner; but they are continually uniting, swelling, and separating. As the rising of the thunder-clouds, the earth is made the scene of a great number of very curious phenomena, that are motionless, or of and whimsical shapes; all these, upon the appearance of the thunder-cloud, draw towards it, and become more uniform in their shapes as they approach; till, coming very near the thunder-cloud, their limbs mutually stretch towards one another, and they immediately coalesce into one uniform mass. Sometimes the thunder-cloud will swell, and increase very fast, without the conjunction of any adiscitious clouds; the vapors in the atmosphere forming themselves into clouds whenever it passes. Some of the adiscitious clouds appear like white fringes, and some with a skin of the thunder-cloud, and are kept continually growing darker and darker, as they approach to unite with it. When the thunder-cloud is grown to a great size, its lower surface is often ragged, particular parts being detached towards the earth, but still connected with the rest. Sometimes the lower surface swells into various large protruberances, bending uniformly downwards. In the same time, one whole side of the sky, the clear parts of it, is so elevated, as it might seem to reach the heaven; and that part towards which the rain commonly falls in the greatest plenty; and if the agitation be exceedingly great, it commonly hail.

1268.  Lightning, when the thunder-cloud is swelling, and extending its branches over a large tract of country, the lightning is seen to dart from one part of it to another, and often to illuminate its whole mass. When the cloud has acquired a sufficient extent, the lightning strikes between the cloud and the earth, in two opposite places, the path of the lightning lying through the whole body of the cloud and its branches. The longer this lightning continues, the less dense does the cloud become, and the less dark its appearance; till at length it breaks in different places, and shows a clear sky. Those thunder-clouds are sometimes in a positive as well as a negative state of electricity. The electricity continues longer of the same kind, in proportion as the thunder-cloud is simple and uniform in its direction; but when the lightning changes its place, there commonly happens a change in the electricity of the apparatus over which the clouds passed. It changes suddenly after a very violent flash of lightning; but gradually when the lightning is moderate, and the progress of the thunder-cloud slow.

1269.  Lightning is an electrical explosion or phenomenon. Flashes of lightning are usually seen crooked and waving in the air. They strike the highest and most pointed objects in preference to others, as hills, trees, church spires, and conducting objects, &c. The direction the lightning forms is not, as is generally supposed, readily than those that are terminated by flat surfaces. Lightning is observed to take and follow the readiest and best conductor; and the same is the case with electricity in the discharge of the Leyden jar, from whence it is inferred, that in a thunder-storm it would be safer to have one's clothes wet than dry. Lightning burns, dissolves metals, renders some bodies, sometimes strikes persons blind, destroys animal life, deprives magnets of their virtue, or reverses their poles; and all these are well-known properties of electricity.

1270.  With regard to places of safety in times of thunder and lightning. Dr. Franklin's advice is to sit in the middle of a room, provided it be not under a metal lustre suspended by a chain, sitting on one chair, and laying the feet on the floor. It is still better, he says, to bring two or three mattresses or beds into the middle to place the end of the bed against the wall, for there are a great number of conductors as the walls the lightning will not be so likely to pass through them. But the safest place of all is in a hammock hung by silken cords, at an equal distance from all the sides of the room. Dr. Priestley observes, that the place of most perfect safety must be the cellar, and especially the middle of it; for when a thunder-storm is on, the lightning strikes on it before it reaches the lower body of the house. In the fields, the place of safety is within a few yards of a tree, but not quite near it. Beccaria cautions persons not always to trust too much to the neighborhood of a higher or better conductor than their own body, since he has repeatedly found that the lightning by no means descends in one undivided track, but that bodies of various kinds conduct their share of it at the same time, in proportion to their quantity and conducting power.
Sect. II. Of the Means of prognosticating the Weather.

1271. The study of atmospherical changes has, in all ages, been more or less attended to by men engaged in the culture of vegetables, or the pasturage of animals; and we, in this country, are surprised at the degree of perfection to which the ancients attained in this knowledge. But it ought to be recollected, that the study of the weather in the countries occupied by the ancients, as Egypt, Greece, Italy, and the continent of Europe, is a very different thing from its study in an island situated like ours. It is easy to foretell weather in countries where months pass away without rain or clouds, and where some weeks together, at stated periods, are as certainly seasons of rain or snow. It may be asserted with truth, that there is a greater variety of weather in London in one week, than in Rome, Moscow, or Petersburg, in three months. It is not therefore entirely a proof of our degeneracy, or the influence of our artificial mode of living, that we cannot predict the weather with such certainty as the ancients: but a circumstance rather to be accounted for from the peculiarities of our situation.

1272. A variable climate, such as ours, admits of being studied, both generally and locally; but it is a study which requires habits of observation and reflection like all other studies; and to be brought to any useful degree of perfection must be attended to, not as it commonly is, as a thing by chance, and which every body knows, or is fit for, but as a serious undertaking. The weather may be foretold from natural data, artificial data, and from precedent.

1273. The natural data for this study are, 1. The vegetable kingdom; many plants shutting and opening their flowers, contracting or expanding their parts, &c. on approaching changes in the humidity or temperature of the atmosphere; 2. The animal kingdom; most of which, that are familiar to us, exhibiting signs on approaching changes, of which those by cattle and sheep are especially remarkable; and hence shepherds are generally, of all others, the most correct in their estimate of weather; 3. The mineral kingdom; stones, earths, metals, salts, and water of particular sorts, often showing indications of approaching changes; 4. Appearances of the atmosphere, the moon, the general character of seasons, &c. The characters of clouds, the prevalence of particular winds, and other signs are very commonly attended to.

1274. The influence of the moon on the weather has, in all ages, been believed by the generality of mankind: the same opinion was embraced by the ancient philosophers; and several eminent philosophers of later times have thought the opinion not unworthy of notice. Although the moon only acts (as far at least as we can ascertain) on the waters of the ocean by producing tides, it is nevertheless highly probable, according to the observations of Lambert, Tolsto, and Cotte, that in consequence of the lunar influence, great variations do take place in the atmosphere, and consequently in the weather. The following principles will show the grounds and reasons for their embracing the received notions on this interesting topic: —

There are ten situations in the moon's orbit when she must particularly exert her influence on the atmosphere; and when, consequently, changes of the weather most readily take place. These are,—

1. The new, and 2. The full moon, when she exerts her influence in conjunction with, or in opposition to the sun.

3 and 4. The quadratures, or those aspects of the moon when she is 90° distant from the sun; or when she is in the middle point of her orbit, between the points of conjunction and opposition, namely, in the first and third quarters.

5. The perigee, and, 6. The apogee, or those points of the moon's orbit, in which she is at the least and greatest distance from the earth.

7. The two passages of the moon over the equator, one of which Tolsto calls, 7. The moon's ascending, and the other, 8. The moon's descending equinox, or the two lunisices, as De la Lande terms them.

9. The boreal lunisice, when the moon approaches as near as she can in each revolution, (or period between one new moon and another,) to our zenith (that point in the horizon which is directly over our heads).

10. The austral lunisice, when she is at the greatest distance from our zenith; for the action of the moon varies greatly according to her obliquity. With these two points Tolsto composed a table of forty-eight years' observations; the result is, that the probabilities, that the weather will change at a certain period of the moon are in the following proportions: New moon, 6 to 1. First quarter, 5 to 2. Full moon, 5 to 2. Last quarter, 5 to 4. Perigee, 7 to 1. Apogee, 10 to 1. Ascending equinox, 13 to 4. Northern lunisice, 11 to 4. Descending equinox, 11 to 4. Southern lunisice, 3 to 1.

1275. That the new moon will bring with it a change of weather is in the doctrine of chances as 6 to 1. Each situation of the moon alters that state of the atmosphere which has been occasioned by the preceding one: and it seldom happens that any change in the weather takes place without a change in the lunar situations. These situations are combined, on account of the inequality of their revolutions, and the greatest effect is produced by the union of the syzygies, or the conjunction and opposition of a planet with the sun, the sun and its orbises, or points in the orbits of planets, in which they are at the greatest, and least distances from the sun. The probabilities of these variations are as follows: New moon coinciding with the perigee, 35 to 1. Ditto, with the apogee, 7 to 1. Full moon coinciding with the perigee, 10 to 1. Ditto, with the apogee, 8 to 1. The combination of these situations generally occasions storms and tempests; and this perturbing power is always in the greater or lesser degree, through the whole revolution of the equator, particularly in the months of March and September. At the new and full moons, in the months of March and September, and even at the solstices, especially the winter solstice, the atmosphere assumes a certain character, by which it is distinguished for three, and sometimes six months. The new moons which produce no change in the weather, are those that happen at a distance from the apogee. As it is perfectly true that each situation of the moon alters that state of the atmosphere which has been produced by another, it is, however, observed that many situations of the moon are favorable to good and others to bad weather.
The situations of the moon favorable to bad weather are the perigee, new and full moon, passage of the equator, and the northern lunisext. Those belonging to the former are, the apogee, quadratures, and the southern lunisext. Changes of the weather seldom take place on the very days of the moon's situations, but either precede or follow them. It has been found by observation, that the changes affected by the lunar situations in the six winter months precede, and in the six summer months follow these.

The octants. Besides the lunar situations to which the above observations refer, attention must be paid also to the fourth day before new and full moon, which days are called the octants. At those times the weather is inclined to changes; and it may be easily seen, that these will follow at the next lunar situation. Virgil calls this fourth day a very sure prophet. If on that day the horns of the moon are clear and well defined, good weather may be expected; but if they are dull, and not clearly marked on the edges, it is a sign that bad weather will ensue. When the weather remains unchanged on the fourth, fifth, and sixth day of the moon, we may conjecture that it will remain till the full moon, even sometimes till the next new moon; and in that case, the lunar situations have only a very weak effect. Many observers of nature have also remarked, that the approach of the lunar situations is somewhat critical for the sick. According to Dr. Herschel, the nearer the time of the moon's entrance, at full, change, or new moon, the nearer the moon is to midnight, the more fair the weather is in summer, but the nearer to noon the less fair. Also, the moon's entrance, at full, change, or new, during six of the afternoon hours, viz. from four to ten, may be followed by fair weather; but this is mostly dependent on the wind. The same entrance during all the hours after midnight, except the two first, is unfavorable to fair weather; the like, nearly, may be observed in winter.

The artificial data are the barometer, hygrometer, rain-gauge, and thermometer.

By means of the barometer, Taylor observes, we are enabled to regain, in some degree at least, that foreknowledge of the weather, which the ancients unquestionably did possess; though we know not the data on which they founded their conclusions.

We shall therefore annex such rules, as have hitherto been found most useful in ascertaining the changes of the weather, by means of the barometer.

The rising of the mercury presages, in general, fair weather; and its falling foul weather, as rain, snow, high winds, and storms.

When the mercury falls, it foretells thunder, in very hot weather, especially if the wind is south.

The rising in winter indicates frost; and in frosty weather, if the mercury falls three or four divisions, there will follow a thaw; but if it rises in a continued frost, snow may be expected.

When foul weather happens soon after the falling of the mercury, it will not be of long duration; nor are we to expect a continuance of fair weather, when it soon succeeds the rising of the quicksilver.

It, in foul weather, the mercury rises considerably, and continues rising for two or three days before the foul weather is over, a continuance of fair weather may be expected to follow.

In fair weather, when the mercury falls much and low, and continues falling for two or three days before rain comes, much wet must be expected, and probably high winds.

The unsettled motion of the mercury indicates changeable weather.

Respecting the words engraved on the register-plate of the barometer, it may be observed, that they cannot be strictly relied upon to correspond exactly with the state of the weather; though it will in general agree with them as to the mercury rising and falling. The words deserve to be particularly noticed when the mercury removes from 'changeable' upwards; as those on the lower part should be adverted to, when the mercury falls from 'changeable' downwards.

In other cases, they are of no use: for, as its rising in any part forebodes a tendency to fair, and its falling to foul weather, it follows that, though it descend in the tube from settled to fair, it may nevertheless be attended with little rain; and when it rises from the words 'much rain' to 'rain' it shows only an inclination to become fair, though the wet weather may still continue in a less considerable degree than it was when the mercury began to rise. But if the mercury, after having fallen to 'much rain,' should ascend to 'changeable,' it foretells fair weather, though of a shorter continuance than if the mercury had risen still higher; and so, on the contrary, if the mercury stood at 'fair' and descends to 'changeable,' it announces foul weather, though not of so long continuance, as if it had fallen lower.

Concavity of the surface of the mercury. Persons who have occasion to travel much in the winter, and who are doubtful whether it will rain or not, may easily ascertain this point by the following observation:—A few hours before he departs, let the traveller notice the mercury in the upper part of the tube of the barometer; if rain is about to fall, it will be indented, or concave; if otherwise, convex or protruberant.

Barometer in spring. Towards the end of March, or more generally in the beginning of April, the barometer sinks very low, with bad weather; after which, it seldom falls lower than 29 degrees 5 minutes till the latter end of September or October, when the quicksilver falls again low, with stormy winds, for then the winter constitution of the air takes place. From October to April, the great falls of the barometer are from 29 degrees 5 minutes to 28 degrees 5 minutes, and sometimes lower; whereas during the summer constitution of the air, the quicksilver seldom falls lower than 29 degrees 5 minutes. It therefore follows that a fall of one tenth of an inch, during the summer, is as sure an indication of rain, as a fall of between two and three tenths is in the winter.

Barometer relative to situation. It must, however, be observed, that these heights of the barometer hold only in places nearly on a level with the sea; for expe-
riments have taught us, that for every eighty feet of nearly perpendicular height that the barometer is placed above the level of the sea, the quicksilver sinks one tenth of an inch: observations alone, therefore, must determine the heights of the quicksilver, which in each place denotes either fair or foul weather.

1285. The hygrometer is of various sorts, but cord, fiddle-string, and most of the substances commonly used become sensibly less and less accurate, so as at length not to undergo any visible alteration from the different states of the air, in regard to dryness or moisture.

A sponge makes a good hygrometer on this account, as being less liable to be changed by use than cord. To prepare the sponge, first wash it in water, and when dry, wash it again in water wherein sal ammoniac or salt of tartar has been dissolved; and let it dry again. Now, if the air becomes moist, the sponge will grow heavier; and if dry, it will become lighter.

Oil of vitriol is found to grow sensibly lighter or heavier in proportion to the lesser or greater quantity of moisture it imbibes from the air. The alteration is so great, that it has been known to change its weight from three drams to nine. The other acid oils, or, as they are usually called, spirits, or oil of tartar, per deliquium, may be substituted for the oil of vitriol.

Steel-yard hygrometer. In order to make a hygrometer with those bodies which acquire or lose weight in the air, place such a substance in a scale on the end of a steel-yard, with a counterpoise which shall keep it in equilibrio in fair weather; the other end of the steel-yard, rising or falling, and pointing to a graduated index, will show the changes.

Line and plummet. If a line be made of good well dried whipcord, and a plummet be fixed to the end of it, and the whole be hung against a wainscot, and a line be drawn under it, exactly where the plummet reaches, in very moderate weather it will be found to rise above such line, and to sink below it when the weather is likely to become fair.

The whalebone hygrometer, originally invented by De Luc, is esteemed one of the best now in use.

1286. The rain-gauge, pluviometer, or hyetometer is a machine for measuring the quantity of rain that falls.

A hollow cylinder forms one of the best-constructed rain gauges: it has within it a cork ball attached to a wooden stem (fig. 76.), which passes through a small opening at the top, on which is placed a large funnel. When this instrument is placed in the open air in a free place, the rain that falls within the circumference of the funnel will run down into the tube and cause the cork to float; and the quantity of water in the tube may be seen by the height to which the stem of the float is raised. The stem of the float is so graduated, as to show by its divisions the number of perpendicular inches of water which fell on the surface of the earth since the last observation. After every observation the cylinder must be emptied.

A copper funnel forms another very simple rain-gauge: the area of the opening must be exactly ten square inches. Let this funnel be fixed in a bottle, and the quantity of rain caught is ascertained by multiplying the weight in ounces by .173, which gives the depth in inches and parts of an inch.

In fixing these gauges, care must be taken that the rain may have free access to them; hence the tops of buildings are usually the best places, though some conceive that the nearer the rain-gauge is placed to the ground the more rain it will collect.

In order to compare the quantities of rain collected in pluviometers at different places, the instruments should be fixed at the same heights above the ground in all such places; because, at different heights, the quantities are always different, even at the same place.

1287. Thermometer. As the weight of the atmosphere is measured by the barometer, so the thermometer shows the variations in the temperature of the weather; for every change of the weather is attended with a change in the temperature of the air, which a thermometer placed in the open air will point out, sometimes before any alteration is perceived in the barometer.

The scales of different thermometers are as follow. In Fahrenheit's the freezing point is 32 degrees, and the boiling point 212 degrees. In Reaumur's the freezing point is 0, and the boiling point 80 degrees. In the centigrade thermometer, which is generally used in France, and is the same as that of Celsius, which is the thermometer of Sweden, the freezing point is 0, and the boiling point 100 degrees. As a rule for comparing or reducing these scales, it may be stated, that 1 degree of Reaumur's scale contains 24 degrees of Fahrenheit, and to convert the degrees of the one to the other, the rule is to multiply by 9, divide by 54, and add 32. One degree of the centigrade scale is equal to one degree and eight-tenths of Fahrenheit; and the rule here is to multiply by 9, divide by 5, and add 32. Any of these thermometers may be proved by immersing it in pounded ice for the freezing point, and in boiling water for the boiling point, and if the space between these points is equally divided, the thermometer is correct.
1288. The study of the weather from precedent affords useful hints as to the character of approaching seasons. From observing the general character of seasons for a long period, certain general results may be deduced. On this principle, Kirwan, on comparing a number of observations taken in England from 1677 (Trans. Ir. Acad. v. 20.) to 1789, a period of 112 years, found:

That when there has been no storm before or after the vernal equinox, the ensuing summer is generally dry, at least five times in six.

That when a storm happens from an easterly point, either on the 19th, 20th, or 21st of May, the succeeding summer is generally dry, at least four times in five.

That when a storm arises on the 20th, 21st, or 22nd of March, and not before in any point, the succeeding summer is generally dry, four times in five.

If there be a storm at S. W. or W. S. W. on the 19th, 20th, 21st, or 22d of March, the succeeding summer is generally wet, five times in six.

In this country winters and springs, if dry, are most commonly cold; if moist, warm: on the contrary, dry summers and autumns are usually hot, and moist summers cold; so that, if we know the moistness or dryness of a season, we can form a tolerably accurate judgment of its temperature. In this country also, it generally rains less in March than in November, in the proportion at a medium of 7 to 12. It generally rains less in April than October, in the proportion of 1 to 2, nearly at a medium. It generally rains less in May than September; the chances that it does so, are, at least, 4 to 3; but, when it rains plentifully in May, as 18 inches or more, it generally rains but little in September; and when it rains one inch or less, in May, it rains plentifully in September.

1289. The probabilities of particular seasons being followed by others, has been calculated by Kirwan, and although his rules chiefly relate to the climate of Ireland, yet as there exists but little difference between that island and Great Britain, in the general appearance of the seasons, we shall mention some of his conclusions.

In forty-one years there were six wet springs, 22 dry, and 13 variable; 20 wet summers, 16 dry, and 5 variable; 11 wet autumns, 11 dry, and 19 variable.

A season is accounted wet, when it contains two wet months. In general, the quantity of rain, which falls in dry seasons, is less than five inches, in wet seasons more; variable seasons are those, in which there falls between 30 lbs. and 36 lbs., a lb. being equal to 157529 of an inch.

January is the coldest month in every latitude; and July is the warmest month in all latitudes above 48 degrees; in lower latitudes, August is generally the warmest. The difference between the hottest and coldest months increases in proportion to the distance from the equator. Every habitat latitude enjoys a mean heat of 60 degrees for at least two months; which heat is necessary for the production of corn.

Sect. III. Of the Climate of Britain.

1290. The climate of the British isles, relatively to others in the same latitude, is temperate, humid, and variable. The moderation of its temperature and its humidity are owing to our being surrounded by water, which being less affected by the sun than the earth, imbibles less heat in summer, and from its fluidity is less easily cooled in winter. As the sea on our coasts never freezes, its temperature must always be above 33° or 34°; and hence, when air from the polar regions at a much lower temperature passes over it, that air must be in some degree heated by the radiation of the water. On the other hand, in summer, the warm currents of air from the south, necessarily give out part of their heat in passing over a surface so much lower in temperature. The variable nature of our climate is chiefly owing to the unequal breadth of watery surface which surround us; on one side, a channel of a few leagues in breadth; on the other, the Atlantic ocean.

1291. The British climate varies materially within itself: some districts are dry, as the east; others moist, as the west coast; in the northern extremity, dry, cold, and windy; in the south, warm and moist. Even in moist districts some spots are excessively dry, as part of Wigtonshire, from the influence of the Isle of Man, in warding off the watery clouds of the Atlantic; and, in dry districts, some spots are moist, from the influence of high mountains in attracting and condensing clouds charged with watery vapor.

1292. The deterioration of the British climate is an idea entertained by some; but whether in regard to general regularity, temperature, moisture, or wind, the alleged changes are unsupported by satisfactory proofs. It is not improbable but the humidity of our climate, as Williams alleges (Climate of Britain, &c. 1816), has of late years been increased by the increase of evaporating surface, produced by the multiplicity of hedges and plantations; a surface covered with leaves being found to evaporate considerably more than a naked surface. If the humidity of the climate was greater before the drainage of marshes and the eradication of forests for agricultural purposes, a comparative return to the same state by artificial planting and irrigation, must have a tendency to produce the same results. However, it will be long before the irrigation of lands is carried to such a degree as to produce the insalubrious effects of unlevied morasses; and as to our woods and hedges, we must console ourselves with the beauty and the shelter which they produce, for the increase of vapor supposed to proceed from them.
BOOK III.

MECHANICAL AGENTS EMPLOYED IN GARDENING.

1293. Having considered the nature of vegetables, and the nature of the materials by which their culture or improvement is effected by art, the next step is to consider the means by which art is applied in the practice of cultivation. In general it may be observed, that every change effected in the circumstances of materials, either consists in, or must be preceded by, a mechanical change in their position. To effect mechanical changes, the fundamental engine is the human frame; but its agency is essentially increased by the use of certain implements, utensils, machines, and buildings. The primary implements of gardening, as an art of culture, would necessarily be confined to a few tools for stirring the ground, and one or two instruments for pruning trees or gathering crops. But in the present state of the art, both the number and kind of agents are greatly extended and diversified. There are tools, instruments, and machines for culture, as the spade, knife, and water-engine; for beautifying scenery, as the broom, scythe, and roller; utensils for portable habitations of plants, or conveying materials, as pots and baskets; structures for culture, as glass frames, hot-houses, and awnings; and buildings for use, convenience, or decoration, as tool-houses, arbors, and obelisks. The whole may be included under implements, structures, and edifices, as in the following Table:—

CHAP. I.

Implements of Gardening.

1294. The usual mechanical agents employed in garden-culture, may be classed as follows:—1. Tools, or simple implements for performing operations on the soil, and other dead or mineral matters; 2. Instruments for performing operations on plants, or on living bodies, as insects and vermin; 3. Utensils for habitations of plants, or the deportation or retention of either dead or living materials; 4. Machines, or compound implements for any of the above or other purposes; and, 5. Articles adapted, manufactured, or prepared, so as to serve various useful purposes.

Sect. I. Tools.

1295. The common character of tools is, that they are adapted for labor which requires more force than skill; they are generally large, and require the use of both hands and the muscular action of the whole frame, often aided by its gravity. Tools consist of two parts, the head, blade or acting part; and the handle or lever, by which the power is communicated, and the tool put in action. As almost all tools operate by effecting a mechanical separation between the parts of bodies, they generally act on the principle of the wedge and lever, and consequently the wedge-shape ought to enter, more or less, into the shape of the head or blade of most of them, and the lever or handle ought to be of some length. Where the handle is intended to be grasped and held firm, its form may be adapted for that end, as in the upper termination of the handle of the shovel or the spade; but where the human hand is to slide along the handle, then it should be perfectly cylindrical, as producing least friction, as in the hoe and the mattock. The materials of which tools are composed, are almost exclusively iron and timber; and of the latter the ash is reckoned to combine most strength and toughness, the willow to be lightest, and fir or pine deal the straightest. The best quality of both materials should, if possible, be used, as scrap-iron and cast-steel, and root-cut young ash from rocky steeps. For light tools, such as the hoe and rake, the willow, or pine deal, may be used for the handles, but in scarcely any case can inferior iron or steel be admitted for the blades.

1296. The pick (fig. 77.) is a double or compound lever, and consists of the handle (a), which ought to be formed of sound ash timber, and the head (b), which ought to be made of the best iron, and pointed with steel. There are several varieties: the first, the pick with the ends of the head pointed (fig. 77.), is used for loosening hard ground, gravel, &c.; the second, or pick-axe (fig. 78.) with both ends wedge-shaped, in reversed positions, and sharp, is used for cutting through the roots in felling timber; the third, or mattock (fig. 79.), is used chiefly for loosening hard surfaces and for grubbing up roots of small trees or bushes. It is sometimes called a crow, and also a grubbing-axe, hoe-axe, &c.

1297. Garden-levers are of two species, the removing and the carrying lever.

1298. The removing-lever (fig. 80.) is a straight and generally cylindrical or polygonal bar of iron, somewhat tapered and wedge-shaped or flattened in the thick end; it is used for the removal of large stones or other heavy bodies, in which its advantage is as the distance of the power (a), from the fulcrum (b), &c.

1299. The carrying-lever, or hand-spoke, is used in pairs for carrying tubs of plants or other bodies or materials furnished with hooks or bearing staples, under or in which to insert the hand-spokes. Two of them united to a platform of boards form the common hand-barrow.
SCIENCE OF GARDENING.

Part II.

of tough root-cut ash timber, rather longer than the handle of the pick, but generally about two feet nine inches. Spades are manufactured of different sizes, and generally with a flat blade; but perforated blades (fig. 82.) are sometimes prized, as cleaning or freeing themselves better from earth in adhesive soils; and semi-cylindrical blades (fig. 83.), or what canal-diggers call grafting-tools, are preferred for the same reason, and also as entering the soil easier, because gradually, and in effect as if a flat spade with a pointed or shield-like curved edge were used. Spades with curved edges or pointed blades are easiest to thrust into the earth in hard or stiff soils, and clean themselves better, but they are more apt to leave untouched parts (baulks) in the bottom of the trench than the common square-mouthed spade. They are the best species for new ground work, but not well adapted for culture.

1301. The shovel (fig. 84.) consists of two parts, the handle and the blade; the latter of plate-iron, and the former of ash timber. There are several species. Such as are turned up on the edges, and are used for shovelling mud, or, when formed of wood (generally of beech), for turning grain, seeds, or potatoes; square-mouthed shovels, for gathering up dung in stables, and used by the gardener in the melon-ground; heart-shaped or pointed-mouthed shovels, used for lifting earth out of trenches in ditch-making, trenching, or in other excavations; and long narrow-mouthed shovels, for cleaning out drains, &c.

1302. The fork. (figs. 85, 86, and 87.) Of this tool there are three principal species: — The first (fig. 85.), for working with litter, haulm, or stable-dung; the second (fig. 86.), for stirring the earth among numerous roots, as in fruit-trees and flower-borders, or for taking up roots; and the third (fig. 87.), for plunging pots in bark-pits, or for taking up asparagus or other roots. The prongs of the last are small, round, and should be kept clear or polished by use, or by friction with sand. In adhesive soils, a strong two-pronged fork (fig. 86.) is one of the most useful of garden-tools, and is advantageously used on most occasions where the spade or even the hoe would be resorted to in free soils, but especially in stirring between crops.

1303. The turf-spade (fig. 104.) consists of a cordate or scutiform blade, joined to a handle by a kned or bent iron shank. It is used for cutting turf from old sheep-pastures, with a view to its being employed either for turfing garden-grounds, or being thrown together in heaps to rot into mould. It is also used in removing ant-hills and other inequalities in sheep-pastures, in parks, or rough lawns. A thin section is first removed, then the protuberance of earth is taken out and the section replaced, which, cut thin, and especially on the edges, readily refits; and the operation is finished with gentle pressure by the foot, back of the spade, beetle, or roller.

1304. The dibber (figs. 88, and 89.) is a short piece of cylindrical wood, obtusely pointed, and sometimes shod with iron on the one end, and formed into a convenient spade-like handle in the other. There are three species. The common garden-dibber (fig. 88.), the potato-dibber (fig. 89.), and the forester’s or planter’s dibber. The forester’s dibber has a wedge-shaped blade, forked at the extremity, for the purpose of carrying down with it the tap-root of seedling trees; it has been much used in planting extensive tracts, but may be considered as a barbarous mode of treating plants, and deserving reprobation. There are also dibbers that make two holes at once, sometimes used in planting leeks or other articles that are placed within a few inches of each other; dibbers which make several holes for planting beans and other seeds; and wedge-shaped dibbers which in soft sandy soils are easily worked, and admit of spreading the roots better than the round kind. These wedge-shaped tools also admit of putting two plants in a hole, one at each extremity.

1305. The planter’s hack, or double mattock (fig. 90.), is used for the same purpose as the forester’s dibber, and is much to be preferred. (See Pontey’s Profitable Planter.)

1306. The planter’s trowel is a triangular blade of iron joined to a short handle, used for planting young trees in free but unprepared soils, as heaths, moors, &c. (Sang’s Planters’ Kalendar.)

1307. The planter’s pick-axe is the tool of that name (fig. 78.) in miniature; or sometimes merely a small mattock (fig. 79.) used for planting in stony uncultivated soils.

1308. The garden-trowel is a tongue-shaped piece of iron, with a handle attached; the blade or tongue either flat (fig. 91.), or semi-cylindrical (fig. 92.), or merely turned up on the sides. It is used to plant, or take up for transplanting, herbaceous plants and small trees. Trowels are also used for loosening the roots of weeds, and are then called weeding-irons. Sometimes they are used for stirring the soil among tender plants in confined situations. Wooden trowels or spatulae are sometimes used in potting plants to fill in the earth; but the garden-trowel with the edges turned up is the best for this and most other purposes.

1309. The transplantor (fig. 93.) consists of two semi-cylindrical pieces of iron with handles, and which are so inserted in the ground as to enclose a plant with a ball of earth between them. In this state they are attached to each other by two iron pins, and, being pulled up, bring with them the plant to be removed, surrounded with a ball of earth.
This being set in a prepared excavation surrounded by loose earth, the transplanter is then separated as at first, and being withdrawn, one half at a time, the earth is gently pressed to the ball containing the plant, and the whole well watered. Tender plants so transplanted receive no check, even if in flower.

1310. **Hoes** are of two species, the draw-hoe and thrust-hoe, of each of which there are several varieties.

1311. *The draw-hoe* ([figs. 94, to 97.]) is a plate of iron, six or seven inches long by two or three broad, attached to a handle about four feet long, at an angle less than a right angle. The blade is either broad for cutting weeds ([fig. 94.]); deep and strong for drawing earth to the stems of plants ([fig. 95.]); curved so as to act like a double mould-boarded plough in drawing drills; formed into two strong broad prongs for stirring hard adhesive soils ([fig. 96.]); or it is formed to accomplish the first and last purposes, as in the double hoe. ([fig. 97.])

1312. *The thrust-hoe* ([figs. 98, and 99.]) consists of a plate of iron attached somewhat obliquely to the end of a handle, either by a bow ([fig. 98.]), or a straight piece. ([fig. 99.]) These hoes, which are sometimes called Dutch hoes, are used only for killing weeds, or loosening ground which is to be afterwards raked. As a man can draw more than he can push, most heavy work will be easiest done by the draw-hoe.

1313. *The wheel-hoe* ([fig. 108.]) is a compound between the draw and thrust hoes, being drawn by one man and thrust by another. It is used for hoeing garden-walks in the Low Countries and France, where the walks are either of sand or earth. In this country it could seldom be employed for this purpose; and indeed for this or any other object it is a bad implement, as it requires two men to work it; and two men working with the same tool will never do as much work as if they used separate tools.

1314. *The garden-rake* consists of a range of teeth inserted in a straight bar of iron or wood from six to eighteen inches in length, and attached at right angles across the end of a handle. Rakes vary in size, and in the length and strength of their teeth, and are used for covering seeds, or raking off weeds or cut grass, for smoothing surfaces and for removing or replacing thin strata of pulverised surfaces as in cufing. For the latter purpose a wooden-headed rake is preferable, for the others iron is generally more eligible.

1315. *The drill-rake* has large coulter-formed teeth about six inches long and the same distance apart: it is used for drawing drills across beds for receiving small seeds, and the same rake serves to stir the soil between the rows after the seeds come up. In very loose soils, where a wide drill is required a sheath of wood may be fixed to the upper part of each prong to spread the earth, but this is seldom necessary. When the drills are required not to be quite so wide as six inches, the operator has only to work the implement diagonally.

1316. *The hoe-rake* combines a hoe and rake, either at opposite ends of the same handle, as in France, or back to back at one end, as in England. ([fig. 100.]) They are used for giving slight dressings to borders.

1317. *The turf-raser* (raser, Fr. to shave or trim.) ([fig. 101.]) consists of a narrow
kidney-shaped blade fixed to a straight handle, and is used for paring the edges of verges or borders of turf; and for cutting the outlines of turfes to be raised with the turf-spađe.

1318. The turf-beetle (fig. 102.) is a cylindrical or conical piece of wood, of one hundred or two hundred pounds' weight, with an upright handle and two cross-handlets attached; it is used chiefly for pressing down and levelling new-laid turf. There is a variety, consisting of a rectangular block with a handle placed obliquely (fig. 103.), which is used when a less powerful pressure is desirable.

1319. The turf-scraper is a head or plate of wood (fig. 105.) or iron (fig. 106.), fixed at right angles across the end of a long handle, and is used chiefly to scrape off earth, or the exuviae of worms, snails, &c. from lawns, grass verges, or walks, early in spring. In some cases, teeth, like those of a saw, are formed in the edge of the blade of such scrapers, in order to tear out the moss from lawns; in many situations, however, a mossy lawn is much to be preferred to grass, as softer, and requiring less frequent mowing. Wire besoms are used with good effect for this purpose, as well as for removing moss from walls or trunks of large trees.

1320. The dock-weeder (fig. 107.) is composed of a narrow iron blade attached to a spade-like handle, with a protruding iron stay joined to the lower end of the handle, or to the iron shank of the blade, to act as a fulcrum. It is used for digging up long conical roots of weeds in pastures or close crops, where the spade or two-pronged fork cannot be introduced; or for taking up crops of fusiform roots, as the parsnep, scorzonera, &c.

1321. The besom used in gardening is of three species. The spray broom, consisting of a small faggot of spray, generally that of the birch, or of spartium, with a handle inserted; or a brush of bristles with a similar handle: the former sort are used for the open air, the latter in hot-houses, seed-rooms, &c. The wire besom consists of a bundle of iron or copper wires, of one twentieth of an inch in diameter, fixed to a long handle. It is used for sweeping gravelled paths which have become mossy, mossy walls, mossy trunks of trees, &c. Such besoms require to be dipt in oil occasionally, to retard the progress of oxidation.

1322. Implement-cleaners, are small spatúlae formed of wood, generally by the operator himself. A small brush of wire like a painter's large brush is useful for cleaning pots, and some have a particular description of knife for that purpose, and for spades, hoes, &c.

1323. Of these tools the essential kinds are the spade, the dung-fork, and the rake; for with these, all the operations for which the others are employed may be performed, though with much less facility, expedition, and perfection. There are diminutive sizes of most of them to be had in the shops for infant gardeners; and portable and convertible sets for ladies and amateur practitioners.

Sect. II. Instruments.

1324. The common character of cutting-implements is, that they require in their use more skill than physical force: they may be divided into instruments for operations, as the knife, saw, &c.; instruments of direction, as the measuring-rod, level, &c.; and instruments of designation, as numbering-tallies, name-pieces, &c.

Subsect. I. Instruments of Operation.

1325. Operative instruments are used in labors of a comparatively light kind. They may be used in general with one hand, and commonly bring into action but a part of the muscular system; the scythe however is an exception. They are similarly constructed to tools, and act on the same principles, differing from those only in being generally reducible to levers of the third kind, or those in which the power or hand is between the weight or matter to be cut or separated, and the fulcrum or arm, as in cutting off a shoot with a knife. But in clipping, the fulcrum is between the hand and the weight or object to be clipt off, and therefore shears act as wedges moved by levers of the second kind. The materials of instruments are in general the same as tools, but the handles of knives are of horn, bone, ivory, or ramose fucus, and the greatest attention is requisite as to the iron and steel of the blades.

1326. The garden-knife is of several species and varieties.

The common garden-knife consists of a blade of prepared steel, fixed without a joint in a handle of bone or horn, and kept in a sheath of leather or pasteboard. It varies in shape and size, and in the quality of the blade; the best in England are generally made in London, but the great mass disposed of in commerce are manufactured at Sheffield. Every working-gardener ought to carry one of these knives in a side-pocket on his thigh, that he may be ever ready to cut off pieces of dead, decayed, or injured plants, or gather crops, independently of other operations.

The common pruning-knife is similar to the former, but less hooked at the point; for though the hook be useful in gathering some crops, and in cutting over or pruning herbaceous vegetables, yet as all knives cut on the same principle as the saw, it is injurious when the knife is used to cut woody shoots: therefore, wherever a clean section is of importance, the pruning-knife, with a straight-edged blade, and not the common garden-knife, with a hooked blade, ought to be employed.

The folding pruning-knife differs from the other, in having the blade jointed in the handle, for the purpose of rendering it portable with greater ease and in any description of pockets; such knives are more
especially used by master-gardeners. There are varieties of these, with saws, chisels, penknives, &c.; the two latter are more curious than useful.

The budding-knife (fig. 110.) differs from the common pruning-knife, in having a thinner and more narrow blade fixed in a bone or horn handle. It is used for grafting, inarching, &c.

115

110

The budding-knife (fig. 110.) differs from the grafting-knife, in having the point of the sharp edge of the blade rounded off in the same manner as is the back or blunt edge of the grafting and pruning knives. It has also a thin wedge-shaped ivory or bone handle for raising up the bark, in the operation of inoculation.

The asparagus-knife consists of a strong blade, fixed in a handle, blunt on both edges, and straight (fig. 111.); or slightly hooked, and serrated at one end. (fig. 112.)

1927. The garden-chisel is of two species, of which there are several varieties.

The grafting-chisel differs from the carpenter's chisel, in being a narrow wedge tapering equally on both sides. It is used to split stocks where the common pruning-knife is not deemed sufficiently strong.

The forest-chisel (fig. 113.) is a sharp edge of steel, with or without a sharp steel hook or hooks, generally called ears: this blade or wedge is attached to a handle, from six to ten feet long or upwards; or better to a handle capable of being lengthened by additional joints. It is used for cutting off small branches of forest-trees close by the bole or trunk; with one hand it is placed and adjusted under the branch, and with the other a smart blow is given by a wooden mallet, which, either at once or by repetition, effects separation, and leaves a smooth section. A variety of this instrument, used for pruning orchards, is furnished with a guard or plate behind the blade, to prevent its entering too far into the trunk or main branch. (fig. 114.)

120

1928. The pruning bill is generally a hooked blade, sometimes sharpened on one and sometimes on both edges, attached to a handle of from one to four feet in length. There are several varieties: one resembles the pruning-knife on a large scale (fig. 115.), having a handle four feet long, and is used for pruning hedges in the best hedge-districts, such as Northumberland and Berwickshire; another (fig. 116.) has a handle of only one, or one foot and a half long, and is sharpened in part on the back, forming a sort of halberd-like blade, and is used where hedges are plashed, as in Middlesex and Hertfordshire; and the last we shall mention, contains a saw on one edge of the blade, and a knife on the other (fig. 117.); of this and the first-mentioned sorts are small portable varieties with cases, &c. for amateur foresters.

1929. The forest-axe is a steel wedge fixed at right angles to the end of a handle of wood, from two and a half to four feet long, and is chiefly used for cutting roots or trunks at the ground’s surface, where the saw cannot operate. Axes vary in dimension, and also in the shape of the head or wedge, which, for the purposes of gardening, ought to be long and narrow.

1930. Occasional instruments. Besides the above there may be wanted, in extraordinary cases, adzes, gouges, carving-chisels, and peculiar-shaped instruments, which the intelligent gardener will search for or procure to be made to answer his intentions.

1931. The pruning-saw (fig. 118.) is a blade of steel, serrated in what is called the double manner on one side, and is either jointed like a folding pruning-knife; jointless as in the common knife; shaped like a carpenter’s saw (fig. 119.); or of some length, say with a handle of six or eight feet, as in the forest-saw. (fig. 120.) The small saws are used for cutting off branches where the knife cannot easily act owing to want of room, and the forest-saw is used in cutting off large branches. In either case the section must be smoothed with the forest-chisel or pruning-knife, and, if possible, or at least in delicate cases, should always be covered with some tenacious air-excluding composition.

1932. The overruncator (fig. 121.) is a compound blade attached to a handle from five
to eight feet in length, and operating by means of a lever moved by a cord and pulley. Its use is to enable a person standing on the ground to prune standard trees, which it readily does when the handle is eight feet long, to the height of fifteen feet; and, by using step-ladders, any greater height may be attained. Branches one inch and a half in diameter may readily be cut off with this instrument. There is a species made entirely of metal, to be used with one hand for pruning shrubs or hedges: of this species there are varieties made at Sheffield of different sizes and qualities.

1333. The shears used in gardening are of several species.

1334. The pruning-shears (fig. 122) differ from the common sort, in having a moveable centre (a) for the motion of one of the blades, by which means, instead of a crushing cut, they make a draw-cut, leaving the section of the part attached to the tree as firm and smooth as if cut off with a knife. It is used in the same way as the common shears, and is very convenient in reducing the size of the shrubs or bushes, and clipping hedges of roses or other select plants.

1335. The ringing-shears (fig. 123) is an instrument of French invention for expediting the practice of ringing trees. A two-bladed knife, with both blades open at once, will give the best idea of its mode of operating, and is, in fact, a good substitute.

1336. The French pruning-shears (fig. 124), by the curvature of the cutting blade, cuts in a sort of medium way between the common crushing and pruning shears: it is an expeditious implement for pruning the vine.

1337. Hedge-shears (figs. 125 & 126) are composed of two blades, acting in unison by means of a pivot, on which they turn, on the principle of a lever of the second kind. They were formerly much used in gardening, for hedges, fanciful figures, bowers, and even fruit-shrubs, which were then shorn or trimmed, into globes, cones, and pyramids, by shears. At present the taste is different. Shears, however, are still wanted for hedges of privet and yew; but where the twigs or shoots are stronger, as in the holly, thorn, and beech, the hedge-bill or pruning-shears is preferable, as producing wounds more easily cicatrised, and not thickening the outer surface of the hedge, by which means the interior shoots rot for want of air, especially in thorn and other deciduous hedges.

1338. verge-shears (fig. 127) are a species in which the blades are joined to the handles by kneed shanks, to lessen stooping in the operator. They are chiefly used for trimming the sides of box-edgings and grass-verters. A variety has a small wheel appended, which in cutting grass-edgings is a great improvement.

1339. turf-shears (fig. 128) are another variety, for cutting the tops of box-edgings and the tufts of grass at the roots of shrubs, not easily got at by the scythe. Some of these have also a wheel or even two wheels on an axle fixed to the shears on the principle of the table-caster.
1340. The scythe (fig. 129.) is a sharp blade of steel attached to the end of a crooked wooden handle. It varies somewhat in size and in the angle made by the plate or knife, which is so contrived as to be varied at the pleasure of the operator; and in mowing very short thick grass, is generally placed so as the plane of the blade may be parallel to the plane of the surface to be mown. 1341. Of the garden-scarifiers, or bark-scarifiers, there are several sorts. They are generally hooked edge-tools or blunt knives, used for removing the already scaling off external epidermis of the stem and branches of fruit-trees of some age. They vary in size and strength, in order to suit different sorts of trees, and different parts of the same tree. The two-handed instrument (fig. 130.) is for removing the bark from the axillae of the branches, or other angular parts difficult to be got at. The small hook (fig. 131.) is for lateral branches of one and two inches in diameter; and the knife-hook (fig. 132.) for the trunks of the largest trees. This operation should be performed in the middle of winter; and to guard against accidents, the whole of a tree should seldom be done in one season.

1342. The moss-scraper, for standards, is a sort of horse curry-comb (fig. 133.); and for wall-trees, is a sickle-like instrument (fig. 134.) In either form it is used to remove moss from the branches, or woody parts of trees; the existence of which is a certain indication of the commencement of decay. It must be confessed, however, that such instruments seldom remove the moss completely, and that the scarifier, by removing a portion of the outer bark, does the business much more effectually, and is greatly to be preferred. 1343. The blunt knife (fig. 135.) has a lanceolate, double-edged blade, somewhat obtuse on the edges, and is used for the removal of decayed wood from hollow wounds in old neglected trees. It can never be wanted where there has been any thing like good management.

1344. Of forest barking-irons there are two species and several varieties. They are used, not to scarify or remove the scaly decaying epidermis, but to remove the entire mass of
cortical layers of the oak for the purposes of the tanner. The first species includes four varieties: the smaller instruments (figs. 136, 137, & 138.) are for undergrowth, or cope bark, or small branches; the largest (fig. 139.) for the larger branches and trunks: the long blade (fig. 140.) is the second species, and is used for cross-cutting the bark, before removed by the scarifiers, into proper lengths.

1345. The garden-hammer consists of a head with a flat face and forked claw, and is generally lighter than the carpenter's hammer. It is used chiefly by gardeners for driving or drawing the nails in dressing wall-trees.

1346. Of fruit-gatherers there are several species. 1347. Saul's fruit-gatherer (fig. 141.) consists of a pair of cutters (a and b) attached to a long pole, which may be lengthened by screwed joints or otherwise. The operating lever (c) may be attached to any part of the pole; the lever of the moving chop (d) has a spring under it to keep it open; and the communicating string passes over a pulley (e); the cutters (a, b) are so connected to the pole by a joint and arch (f), that they may be set at any angle required, for the purpose of getting at the fruit readily. Half the top of the basket may be covered to prevent the fruit from falling out when a full basket is brought down.

1348. Lane's fruit-gatherer (fig. 142.) consists of a pole (a), with a pair of forceps (b, c) at the end; one forcep (b) being fixed, and the other (c) moveable; a wire (d, d) is attached to the moving forcep, which passes along a groove to the trigger (e). The pole being raised by the left-hand, the back of the right raises the trigger, and opens the forcep, which, being applied to the fruit, the trigger is pressed, by which the fruit is secured. The forceps are formed of a ring of metal, covered with soft leather and padded.

1349. The orange-gatherer used in Spain (fig. 143.) consists of a rod with a cup at the end, composed of six lingulate pieces of plate-iron or hoop, somewhat sharp at the edges. The instrument is made to enclose the fruit, the stalk being between the ironplates; a gentle twist is then given, when the fruit is detached and brought down in the cup.

1350. The Swiss fruit-gatherer (fig. 145.) is a small basket, with the ends and edges of the ribs sharpened and protruding; it is used like the orange-gatherer, in collecting apples, pears, and walnuts. (Lasteyrie, Collect. de Mach. &c.)

1351. The orchardist's hook (fig. 144.) consists of a rod, with an iron hook fixed at one extremity, and a sliding-piece (a) at the other. The operator being on the tree, seizes a branch with the hook, draws it towards him, and holds it in that position till he gathers the fruit, by hooking on the sliding cross-piece to another branch. This slider passes freely along the rod, but cannot drop off on account of the pin (b) at the end.

1352. Garden-pincers are of three species; those for drawing nails do not differ from those used by carpenters, consisting of two hooked levers of iron, acting as levers of the first kind; those for twisting wire in repairing trellis or flower-baskets, &c. are the sort used by wire-workers, which operate both as pliers and pincers; and those for pulling
weeds are, when large (fig. 146.), formed of wood pointed with plate-iron, and are used for pulling out large weeds, particularly thistles and other large plants in hedges, or other bulky crops. They are also sometimes used for common weeding, to prevent stooping and treading beds and borders; but their chief use is to weed ponds, either reaching from the shore or from boats. A small sort formed of iron is sometimes used for weeding very hard gravel-walks. Gloves, having the first finger and thumb points, with iron or steel, brought to a wedge shape, are also used for the same purpose.

1353. The grape-gatherer (fig. 147.) is a pair of scissors, combining also tweezers or pincers, attached to the end of a rod six or eight feet long, and worked by a cord and pulley, or lever and wire. The bunch of grapes to be gathered from the roof of a lofty vinery, or the sprig of myrtle to be culled from the summit of a green-house stage, is not only clipped cleanly off the plant by the shears, but held fast by that part of them acting as pincers till it is brought down to the operator.

1354. The peach-gatherer (fig. 148.) consists of a tin funnel or inverted hollow cone, fixed on the end of a rod or handle at an obtuse angle, the funnel is first introduced under each fruit, and then gently raised or moved sideways; if ripe, the fruit will fall into the funnel. It is used for gathering the peach tribe, apricots, and plums.

1355. The pear-gatherer resembles the above, but the funnel is deeply notched or serrated, in order to aid in gently drawing off ripe fruit. It is used in gathering the finer sorts of pears and apples from walls. This and the last instrument are also sometimes used for gathering mulberries. Common pears and apples are often gathered by Lane's instrument. (figs. 142. & 151.)

1356. The berry-gatherer (fig. 149.) is the combined scissors and pincers above mentioned, worked by the hand like common scissors, and is used for gathering gooseberries, strawberries, raspberries, and such fruits as should be touched by no other hand than that which conveys them to the mouth. Some opulent proprietors have branches of fruit shrubs cut off and brought to table, as bouquets, in elegant china vases; or have their strawberries grown in pots, and thus served up to be gathered as used, &c. Jerome Buonaparte, when king of Westphalia, passing through Warsaw, on his way to Moscow, in the campaign of 1812, had branches of cherry-trees laden with fruit held upright by soldiers round his table like a sort of grove, from the branches of which, extending over their heads, he and his guests gathered the fruit.

1357. The seed and cherry gatherer (fig. 150.) consists of a valvular pocket placed on the end of a long rod. One valve or jaw of the mouth or pocket is fixed, and the other is kept open by a spring, and closed at pleasure, and made to bite or pinch off seeds of forest-trees, or even fruits, especially cherries, by operating on it with a string and pulley, or wire and lever. It is peculiarly useful for gathering ash and sycamore keys, haws, and such like seeds.

1358. Flower-gatherers are of two sorts, the long-handled and the small flower-gatherer. The latter may be the same implement as the berry-gatherer. (fig. 149.) The long-handled flower-gatherer (fig. 152.), and which is also an excellent grape-gatherer, cuts and holds on the same principle as the wire-worker's pincers, or berry-gatherer. It is worked by means of two small cords, one (a) serves to vary the direction of the cutting part or scissors, and the other (b) to effect the amputation and retention of a flower, twig, or bunch of fruit.
1359. The climbing-spur (fig. 153.) is of two sorts, one with, and the other without a stem. The first sort (a) is fastened to the upper part of the leg with a leather belt (b); the other sort (c) is tied to the feet. By means of these spurs, one on each foot, naked-stemmed trees may be ascended to any height, and when it is wished to stop a short time at any part, the screw of the ring (d) is entered in the trunk, and forms a firm point for one foot. (Lasteyrie, Coll. de Machines, &c.)

1360. The essential operative instruments are the knife, saw, shears, scythe, and hammer.

**SUBSECTION 2. Instruments of Direction.**

1361. The common characteristic of directive or preparatory instruments is, that they are used in actions preparatory to operations, rather than in operations themselves, and depend on scientific knowledge more than on practical dexterity; this remark will apply also to their construction, which is founded on the doctrines of quantities, gravitation, &c.

1362. The garden-line is composed of three parts, the frame, generally of iron, the cord which is wound upon the frame, and the pin which terminates the cord. The common use of the line is perfectly understood from the name; though generally used for straight lines, yet it is also applied, by means of pegs or small stakes, to form curved lines.

1363. The ground-measure. Of this there are at least three sorts used in gardening. A Gunter's chain of 100 links, or 66 feet, a rod of one twelfth, or any equal part of the chain, marked with links on one side, and feet on the other, and a common pocket-rule. To these may be added a pocket measuring-line, though it is not, from its contraction and expansion, to be much depended on. The chain is used to ascertain the contents of, or to lay out and subdivide considerable plots; the rod for the detail of such plots, or for marking out rows, &c.; and the pocket-rule for taking smaller dimensions.

1364. Of timber-measurers and dendrometers there are various kinds, and their use is for taking the dimensions of standing timber without climbing the tree. Broad's measurer (fig. 154.) is composed of two pieces of deal about 13 feet long, with a brass limb or index (a), on which are engraved figures denoting the quarter girth in feet and inches. Raising the instrument, the index end (a) is taken hold of, and the other applied to that part of the trunk where the girth is to be taken, opening it so wide as just to touch at the same time both sides of it, keeping the graduated index uppermost, on which the quarter girth will be shown, allowing 1 inch in 13 for the bark. (Trans. Soc. Arts, vol. xxi. p. 20.) There are various other dendrometers, among which is a curious one by Monteath, which will be afterwards noticed. The above we consider as much the best.

1365. For taking the height of a tree. Rods of deal or bamboo, seven feet long, made so as to fit into ferrules at the end of each other, tapering as in a fishing-rod, may be used. Five of them with feet marked on them would enable a man quickly to measure the height of a trunk of more than 40 feet, as he would reach above seven feet.

1366. The ground-compASSES (fig. 155.) are generally made of hard wood, such as oak, shod with iron, and with an iron gauge or segment (a); their length may be six feet; they are used chiefly for laying out parterres in the ancient manner; since, by a previous
preparation of the soil, the curvilinear parts of such parterres can be described by them with perfect accuracy. The stationary foot is placed on a slip of board a few inches square, with a pin beneath to retain it in its place, and a lead cap above for the point of the foot.

1367. The borning-piece (fig. 156.) is composed of the body (a), commonly a thin slip of board, four inches wide, half an inch thick, and four feet two inches long; the head (b) of a similar slip of board placed across, but only eighteen inches long; and the foot is either of the same form as the head, or merely the squared end of the body (as in the figure). The upper and under edge of the head and foot must be perfectly straight, and form right angles with the edges of the body. Borning-pieces are used to prove, complete, and continue level lines, or lines on certain given slopes. One is placed at each end of a convenient length of the level or slope, and there held perpendicular to its surface, and others, being placed in the interval, and in the same line or vertical plane, the ground under the feet of the intermediate borning-pieces is raised or lowered till it is brought to the proper level or slope, when the upper edges of all the heads will range. Where box-edgings are to be planted with accuracy and beauty, the use of these implements cannot be dispensed with.

1368. Of levels (figs. 157 & 158.) there are a variety of sorts; but the most convenient is half a square, with an iron index in the angle marked with ninety divisions or degrees. The use of these degrees is to facilitate the laying out of slopes; at a perfect level the plummet will hang at 45°, and for a slope it may be any lesser number in ascending, or any greater number in descending from a fixed point. This level may also be used as a square to set off right angles, or indeed angles of any description.

1369. The adjusting horizontal level (fig. 157.) is peculiarly useful in laying out roads, or regulating the slope of lawns or borders, as is also the following instrument.

1370. Dalsieét's level. (fig. 159.) This is an instrument of a very simple description, lately invented, for ascertaining the relative elevation of unequal surfaces. It consists of a wooden bar (a) with a foot at one end (b), and at the other another larger foot with a groove and scale (c), to which the bar is connected by a screw and nut. In using this instrument, two points of different altitude being chosen, the support of the bar (b) is to be placed on the higher, and (c) the foot of the scale on the lower, while the position of both is secured by a slight turn of the thumb-screw. The bar being brought parallel to the horizon with the plummet (d), will indicate, that the upper part of the scale is to be advanced, or the reverse, keeping its foot on the point of support, until some one of the graduations coincides with, or is visibly parallel to the upper edge of the bar. The difference of altitude sought is seen in figures, without calculation. Any person that understands the use of a level will see a variety of levelling operations on a small scale that this implement is calculated to simplify: for example, if it be required to construct an inclined plane, rising an inch in a foot, the inner edge of the scale is to be brought six feet from the foot end of the horizontal piece, and rendered perpendicular to it, by making the graduated line at six inches coincide with the horizontal edge of the bar. Being fixed immovably by the screw in that position, the surface of the ground is then to be worked until the plummet hangs perpendicularly. The first six feet of the inclined plane having been thus constructed, other portions are to be taken successively throughout the remainder. If a plane of a different inclination is required, as of half an inch in a foot, the scale is to be shifted to three inches, and so on. (High. Soc. Trans. vol. v. p. 575.)
1371. The spirit-level, with a theodolite, compass, and telescope, is used for laying out extensive scenes. The most convenient are put together, and assume the form of a stout walking-stick. Small calder is at present the best London artist in this line.

1372. The staff is used in laying out straight lines. It may be a straight rod of six or eight feet long or upwards, and one inch in diameter; with the first six inches at the top painted white, the second black, and the third six inches red. Two points of the desired straight line being found or given, any greater number of points are found by placing other staffs or rods so as they shall range, and the first staff conceal from the eye placed behind it, all the rest in the line; the use of the three different colors is to render the ends distinctly visible when the ground is fresh dung, white or covered with snow, or green, as in pastures.

1373. The straight-edge, for a garden, may also serve for a plumb-rule. It is merely a slip of board with straight parallel edges and sides, of any length from four to ten feet, with the addition of a plummet for occasional use as a plumb-rule. It is used to form and prove smaller levels, between points settled, by the borning-pieces; or to prove beds or borders of even or plane surfaces. As a plumb-rule, this implement is also used to place espalier rails, temporary walls of boards, and even standard trees, upright.

1374. The stake is any straight piece of wood of an inch or two in diameter, and from one to four feet in length. There are two sorts, the one short and thick, of one foot or eighteen inches in length, and used, by being driven into the ground in levelling, as resting-places for the level, or fixed indications of surface alterations; the other, comparatively slender and long, may either be covered with white-wash, or the lower half dipped in white-wash, and the upper half in a black-wash, or they may be painted as the staffs. The last kind are used for tracing out lines of any description, or for indicating the situations of trees, or other objects. Twigs and bits of lath are commonly used as substitutes, but wherever correctness is any object, the trifling expense of two or three hundred of such stakes, should not deter from procuring them.

Subsect. 3. Instruments of Designation.

1375. The object of designating instruments is to record and render ascertainable the individuality of objects, and chiefly of plants; either as species, genera, or varieties. A tally or stake driven into the soil and remaining fast, is, mechanically considered, a wedge held in equilibrium by the resistance of the earth. Wherever there is a variety of plants cultivated, it becomes necessary to be able to mark and distinguish them, as well when in a growing state, as when in a state of hibernation, or recent insertion in the soil.—In sending plants to any distance, the same thing is requisite. For both purposes the name is either written on some instrument, and attached to or placed beside the plant; or a number is made use of instead of the name, from which reference is made to a written list. Of both these a considerable variety is used in gardening.

1376. Notch numbering-sticks are of several distinct species.

1377. The common tally (tailler, Fr.), or number-stick (fig. 160.), is a slip of lath, or deal, or a piece of a rod, nine or twelve inches long, sharpened at one end and squared at the other. The numbers, to nine inclusive, are cut on the face with a knife in Roman numerals (I, II, III, IV, V, VI, VII, VIII, IX.); reading always from the insertion, or sharpened end. Ten is formed by a notch or tally on the near angle, and placed behind the above numerals, extends the series from eleven to nineteen. Twenty is formed by two notches, thirty by three, and so on: the nine numerals above being
placed after the notches, so as to form the intermediate terms of the series. Fifty, instead of five notches, is formed by a cross cut, or channel, like I, on the face, with a similar one on the right side joined to it. One hundred is formed by joining to these two cuts a similar cut on the other side, that is a channel continued on three sides; and one hundred and fifty, by a cut or channel continued on the four sides of the stick. Ninety may be more readily formed by using the mark for one hundred, and placing a notch behind it, to signify 100 less 10, than using the cuts for fifty, and adding four notches before. Other high numbers may be simplified in the same manner. A little reflection will show that this mode of numbering may be carried to almost any extent; and in some nurseries, particularly in Scotland, we have known it carried as far as five hundred, which is formed by only three rings for $150 \times 3 = 450$, and a half ring for 50. Particular attention must always be had to read from the root, or insertion end.

1378. Seton's botanic tally (figs. 161. to 165.) is a highly improved method of numbering, devised by Alexander and George, sons of the late Dr. Anderson. It proceeds upon the same general principles as that above, but with different marks, the ten cyphers (fig. 162.) being denoted by as many single distinct cuts of easy and expedients execution; and any number, however high, requiring no more marks than it would require figures written with a pen.

1379. As an example of application, the number 590 (fig. 161.) may be referred to. "The only way in which the memory is apt to misgiv, in this scheme, is by confounding / & \( \times \) \& \( \times \), \& \( \times \), \& \( \times \), \& \( \times \), with each other, (as a child would confound the figures 6 and 9,) but this slight inconvenience will be remedied by the following key, which may be easily borne in the mind. Let us recollect that, in writing, we naturally draw a stroke from the right, at top, to the left, at bottom, thus /, and not in the opposite direction, thus \( \div \), in all the above numbers, which differ from each other in the direction of the diagonal line, that which is in the direction usual in writing precedes the other, thus \( / \div \) \& \( \div \), \& \( \times \), \& \( \times \),; the other two, \( \div \) \& \( \times \), will not be confused, on recollecting that \( \times \) is the usual numeral notation of five.

In order to express the numbers which refer to a botanical catalogue, a practice of great use to every cultivating botanist, "we cut the stick in the form of a prism of four sides, whereof one is narrower than the rest; or of a triangle, with one of the angles cut off. A transverse section of the tally should be a truncated triangle. (fig. 162. a.) On the narrowest side, notch the number corresponding with that of the genus, in the catalogue. Its being rather more easy to cut the numbers on the smaller than on the larger surface, is the reason for preferring the former for the genus, the number of which is, in most cases, greater than that of the species. On the opposite and wider side, put the number of the species; and if there be a variety, put it on one of the intermediate sides. By this simple method, in going over the garden with the catalogue in our hand, we can see at once the genus, species, and variety of any plant we wish to look for; and in putting in plants, we have always the means ready at hand of placing the numbers with them, without the apparatus of whitened tallies, with ink, blacking, or any of those troublesome expedients in common use. The sticks themselves, which may be painted of a dark color, and kept always at hand, are, besides, less conspicuous and unsightly than the usual large white marks with writing on them, and they are not so easily effaced." (Hort. Trans. vol. ii. p. 248, 349.)

1380. The written number-stick (figs. 166. to 170.) varies in form, size, and materials. The first sort (fig. 166.) is a flat piece of lath, smoothed and pointed with the knife, and either painted, or more commonly rubbed on the face with white lead at the time of using, and numbers corresponding with those of genus, species, and varieties are written on it with a lead pencil. Sometimes types and printers' ink are used: when the paint is dry, common ink, or black paint is also made use of; and in some cases the number is impressed by a cold type, or burnt in by one heated to redness. A little white lead rubbed on with the finger, and the name immediately written with a hard black lead pencil, will last as long as the wood, and is on the whole the best mode. Various sizes are used; from laths formed with the knife three inches long, and half an inch broad, to pieces sawed out of deal, two or three inches broad, and from eighteen inches to three feet long; the upper part painted white, and lower part painted, charred, or coated with some preservative liquid, for durability. With respect to materials, fir deal is most commonly used, but oak boards, or old oak spakes are occasionally made use of in botanic gardens. Cast-iron is also used, and found by nurserymen to be in the end the most economical. Earthenware, hoop-iron, lead, and copper have been tried. The general form in all these cases, is a parallelogram pointed at the insertion end, and somewhat rounded at the other. To detect stealing, or mark appropriation, the name of the proprietors or of the garden may be cast on the back of all lead, or cast-iron, or earthenware naming-instruments.

1381. The stamped numbering-instrument is formed in various ways; the simplest and most economical is that of triangular slips of lead clipt or stampt from sheet-lead of 4lbs. to a superficial foot; and for plants in pots, they need not be longer than three inches, nor broader at the head than half an inch. On these the number is stamped with a type, or the name at length may be stamped in the same manner. Such tallies are durable, unobtrusive, and not so readily driven out of pots as those of wood; for herbaceous plants they may be of double size and weight.
1382. Number-bricks. For plants in the open ground, bricks set endways and rather obliquely in the soil, and the number painted on a black or white ground, answers well where they do not require to be often removed. This mode is extensively used in the herbaceous and tree arrangements in the nurseries of Messrs. Loddiges.

1383. The name-stick differs from the number-stick in having the name written or printed at length, instead of a number, figure, or sign referring to some list or catalogue containing the name. Any of the written number-sticks will serve also for a name-stick; but frequently the upper end is broader, square, round, or oblong, (figs. 167, 168, & 170.) and inclined to the stem, so as the name may meet the eye at a parallel angle for reading. A very neat sort of naming-instrument for plants in hot-houses, which do not require to be often removed, is formed of white earthenware, on which the name may be written with ink or pencil, or printed. A variety of other devices for numbering and naming planted plants, by instruments inserted in the ground, might be mentioned: in the garden of the Ducal Palace Pitti, at Florence, the name, &c. is printed on slips of paper, and placed inside a small glass bottle, which is fixed on the end of an iron rod, a complex mode, and one which can only succeed in climates like that of Italy.

1384. For writing the figures or letters on small sticks, a little white lead is rubbed on with a bit of stiff leather, and a hard pencil is then used; on a larger scale, and on durable materials, the stick is first painted, and the figures or letters afterwards put on in oil colors. On earthenware instruments either ink or oil color may be used. On large sticks the skeleton type may be used. This is the practice in the Paris garden; the classes, orders, and generic name are cut out of one thin plate of brass, which is applied to the face of the stick, and then oil color brushed over it: the specific name is then added in separate letters, from an alphabet so cut or stamped out of brass lamina.

1385. The plant-label is distinguished from the number and naming sticks, in being hung or tied to the plant, or nailed, or otherwise fixed to the wall or trellis against which it is trained. There are two species or varieties, the permanent and temporary.

1386. The permanent label is a slip or plate an inch or more in width, and two or three inches long, of deal, metal, earthenware, leather, horn, bone, ivory, &c. on which the number or name is impressed or written, and it is then hung to trees or nailed on the wall or espalier rail to which trees are trained. The difficulty in the case of hanging labels on trees, is to find a durable tie, or thread, and for this purpose, untanned leathern thongs or catgut is preferred; silver or lead wire may also be used, the former for select plants, and the latter for commoner cases.

1387. The temporary label is a shred of paper or parchment, and sometimes of leather, with a string attached, and is used chiefly by nurserymen to designate plants sold.

1388. The mode of naming or registering by series, chiefly applies to fruit-trees in kitchen-gardens or orchards, and is done by marking down the names in a book or on a plant, in the same order in which the trees or shrubs are planted in the garden. Thus, suppose the east side of an east wall is to be planted and registered without the use of naming-instruments or labels. Begin at the south corner and write down under that title the sort of trees in the order in which they are planted, placing in the list a number against each name in regular series. Suppose that at any time afterwards, you wish to find which tree is the golden pippin; then looking in the list, that name is found opposite No. 9; counting nine, therefore, from the south corner, will give you the tree, &c. This mode of registering by series is always a very good check to any other mode of numbering or naming. Sometimes it is done on a general plan of the garden, but the plan must then be on a large scale to admit of writing down all the numbers or names of the trees in the spots where they are planted.

1389. The essential instruments of direction and designation are the line, rule, level, and common tally.

Sect. III. Utensils.

1390. Utensils may be characterised by their property of being adapted to hold, contain, or include some material or thing, and either for the preparation of materials, the deportation of plants and garden-productions, or their culture and protection.

Subsect. 1. Utensils of Preparation and Deportation.

1391. Preparatory utensils are the screen and sieve. Their construction and use embrace a variety of operations, mechanical and chemical.

1392. Screens are used in gardening for fining or sorting earths, gravel, or tanners' bark. The mould-screen (fig. 171.) is a wire frame with a jointed fulcrum, by which it can be placed sloping to any required degree; its use is to separate stones and coarser particles from mould, either in trenching over ground intended for bulbous or other tender and succulent roots, or in turning over compost-heaps. The soil must be well broken with the spade before thrown on the screen, and it is in vain attempting to use the utensil, unless the earth is dry.
1393. In gravel-screens the wires are placed wider, according to the use to which the gravel is to be applied. In general, one quarter of an inch is the width for earth, and half an inch for garden-gravel; but for gravel used in the highways, one inch is not too wide for excluding small stuff, nor two inches too narrow for admitting the stonelets to be used.

1394. Garden-sieves are of various kinds. The mould-sieve, is a piece of cloth of wire firmly attached to a circular rim, and the holes or interstices need not be above one fourth of an inch in diameter. It is used for sifting mould for small pots; sieves are also required in gardening, for cleaning seeds; and wooden sieves of different kinds for airing or keeping fruit.

1395. Utensils of deportation are, the mould-scuttle, pot-carrier, basket, and packing-case.

1396. The mould-scuttle is a wooden box for carrying sifted earth in situations where the wheelbarrow cannot be brought into use. Sometimes it is made of iron, like the common coal-scuttle.

1397. The pot-carrier is an oblong board, with a hoop-handle in the middle: it is used for carrying pots of plants from one part of the garden to another. A wire sieve answers the same purpose; but it is an ill application of that utensil, and besides occupies both hands, and requires stooping.

1398. Garden-baskets are of several species and varieties, used for growing, carrying, measuring, or keeping vegetable productions. They are woven or worked of the spray, bark, or split woody fibre of trees, or of the young shoots of willow, hazel, and other shrubs.

1399. The plant basket is a vessel of wicker-work, and shaped like a large pot, not less than eighteen inches wide, by twenty inches deep, and is used by some nurserymen, and particularly by the Dutch, to grow large peach-trees, vines, &c. for deportation. By the means of these baskets, when new garden-walls or hot-houses are built, one, and often two years, may be saved in the fruit-trees; the mode is at present a good deal out of use, but deserves to be revived.

1400. The planters’ basket is a flat, rectangular utensil of wicker-work, or boards partitioned into three or more parts, for the purpose of carrying with the gardener when about to plant or remove plants. One division is for the plants taken up; another for the plants to be planted; and a third, for the tools which he uses, and for any decayed parts of plants, stones, weeds, or other refuse. By using such a basket the young gardener may proceed in his operations with order, accuracy, and neatness.

1401. The mould-basket is a strong reticulated utensil of unpeeled willows or hazel, used for carrying earth, gravel, or tanners’ bark.

1402. Carrying-baskets and package-baskets are of various sizes, shapes, and qualities of material and workmanship. Such as are large, coarse, and without handles are called hampers, and about London, boats, barge, and other local names.

1403. Measuring-baskets are chiefly in use by market-gardeners; the largest are bushels and half-bushels, formed of unpeeled or peeled willow shoots or withies; pecks and half-pecks are formed of peeled withies; and sieves, punnets, pottles, and thumbs, for the more rare culinary vegetables and fruits, are formed from shavings of woody fibre.

1404. The plant packing-case is of various species, according as plants in a growing state, plants in a state of rest, and with or without leaves, cuttings, bulbs, or other roots, or seeds, are to be packed. Each of these species varies also according to the distance to which it is to be sent, climate, season of the year, and mode of conveyance. In sending plants in leaf from this country to the continent, and the contrary, a close-bottomed box hooped over (fig. 172.), is generally used; the cover of the upper part being either netting, or if matting very frequently removed.

1405. The glazed packing-case is the most suitable for importing plants from distant countries. One of this kind employed by Sir R. Farquhar, in sending plants from the Mauritius to the Horticultural Society (fig. 173.), was made of inch boards, three feet long, four feet wide, and twenty inches deep. The sloping roof consisted of two glazed shutters.
(a, a, a), which opened to admit air (b), and could be covered at pleasure with two rolls of tarpawling (c, c); the trees were planted in wooden boxes just large enough to contain a single plant and perforated in their sides and bottom (d), and their surface was carefully covered with moss (e), tied down with cord.

**SUBSECT 2. Utensils of Culture.**

1406. The *utensils used in growing plants* are the pot, water-saucer, box, tub, watering-pot, and syringe.

1407. Of *flower-pots* there are several species and many varieties.

The common flower-pot is a cylindrical tapering vessel of burnt clay, with a perforated bottom, and of which there are ten British sorts, distinguished by their sizes thus:

<table>
<thead>
<tr>
<th>Size</th>
<th>In.</th>
<th>In. dia.</th>
<th>In. dia. dep.</th>

</tbody>
</table>

*Common flower-pots are sold by the cast,* and the price is generally the same for all the 10 sorts; two pots or a cast of No. 1, costing the same price as eight pots, or a cast of No. 11.

The store-pot is a broad flat-bottomed pot, used for striking cuttings or raising seedlings.

The pot for bulbous roots is narrower and deeper than usual.

The pot for aquatics should have no holes in the bottom or sides. The pot for marsh-plants should have three or four small holes in the sides about one third of the depth from its bottom. This third being filled with gravel, and the remainder with soil, the imitation of a marsh will be attended with success.

The stone-ware pot may be of any of the above shapes, but being made of clay, mixed with powdered stone of a certain quality, is much more durable.

The propagation-pot is chiefly used for ornament; they are generally glazed green, but, for superior occasions, are sculptured and painted, or incrusted, &c.

1408. The *propagation-pot* (fig. 175.) has a slit in the side, from the rim to the hole in the bottom, the use of which is to admit a shoot of a tree for propagation by ringing in the Chinese manner. Opposite to the slit is an ear, or round appendage, with a hole for hanging the pot to a branch. To those who practise the mode of rooting shoots without laying them down to the ground, such pots will prove very convenient.

In France and Italy they are formed in a similar manner, and for the same purpose, of tinned iron, and by such means they propagate the camellia, banksia, &c.

The square pot is preferred by some for the three smallest sizes of pots, as containing more earth in a given surface of shelf or basin; but they are more expensive at first, less convenient for shifting, and, not admitting of such perfection of form as the circle, do not, in our opinion, merit adoption. They are used in different parts of Lombardy and at Paris.

The classic pot is the common material formed into vases, or particular shapes, for aloes and other plants which seldom require shifting, and which are destined to occupy particular spots in gardens or conservatories, or on the terraces and parapets of mansions in the Summer season.

The Chinese pot is generally glazed, and wide in proportion to its depth; but some are widest below, with the saucer attached to the bottom of the pot, and the slits on the side of the pot for the exit of absorption of the water. Some ornamental Chinese pots are square at top and bottom, and belled out in the middle.

The French pot, instead of one hole in the centre of the bottom to admit water, has several small holes about one eighth of an inch in diameter, by which worms are excluded.

1409. *Flower-pot gauge.* (fig. 174.) In order to form pots of different sizes of a regular ratio to each other, Knight has suggested a plan, of which this may be considered the substance. Assume as a convenient proportion as to width at top, bottom, and height, 8, 5, and 6; lay down the vertical section of a pot of this proportion on a board or large paper; from its centre (a) draw two lines (b and c) passing through the bottom of the sides and equal distances measured on these lines will give equal accretions to smaller or larger sized pots. Knight considers 2 inches as forming a proper difference in diameter in the scale of sizes of pots, which is nearly double that in common use.

1410. The *flower-pot saucer* is a flat circular vessel, with a rim from one to two inches high, and is made somewhat larger than the bottoms of all the above sorts of pots. Its chief use is to prevent the water, which escapes by the bottom of the pot, from proving inconvenient on the shelves or stages in rooms or particular situations. In gardens they are seldom wanted. A species named the *carnation-saucer* (fig. 176.) is formed as much larger than the pot to be placed in it to admit of surrounding its base with water, in order to prevent creeping insects from getting at the pot. In the centre of the saucer is raised a basement on which to place the pot, in order to keep it dry, &c.

1411. The *qualities and durability of pots and saucers* depend on the sort of clay and degree of burning, in which a knowledge can only be acquired by observation and experience. Pots too much burned, crack and fall in pieces; and those which are not burnt enough, splinter or scale off with the frost and continued moisture. Porous earthenware is most congenial to the plants; but by admitting transpiration by the sides,
dries the earth within sooner. Glazed or stone-ware pots are not congenial, but retain moisture a long time.

1412. *The plant-box* (figs. 177, 178, & 179.) is a substitute for a large pot; it is of a cubical figure, and generally formed of wood, though in some cases the frame is formed of cast-iron, and the sides of slates cut to fit, and moveable at pleasure. Such boxes are chiefly used for orange-trees. The construction of those of Versailles is generally approved. Two of the opposite sides are fixed, the other two are moveable, but kept in their places by a couple of iron bars with hinges, which are fastened on one side, and on the other are hooks to catch in (fig. 177.), that the state of the roots may be readily examined, the old earth taken out, and fresh put in at pleasure. Another material advantage gained in these boxes is, that the plants may be shifted by sliding them into others.

1413. *The plant-tub* (fig. 180.) is a circular utensil formed by the cooper for the same purpose as the plant-box. In shifting, the box is unhooped, and when the old earth is removed it is refitted on the same or a new bottom by the cooper.

1414. *The garden watering-pot* is of different species. *The common watering-pot* is a tinned iron or copper vessel, used for conveying water to plants. There are several varieties; but the principal are, 1st, the common large pot, with two roses of different sizes, the one pierced with small, and the other with large holes; 2d, the long spouted pot, for watering plants in pots, at a small distance, either with or without a rose; and, 3d, the shelf watering-pot, which is a small cartouche-shaped pot for watering plants on shelves, or the back part of stoves, close under the glass, consequently above the eye of the gardener.

1415. *The French watering-pots* (figs. 181, 182, & 183.) are generally formed of copper, and some (fig. 183.) have zig-zag spouts, to break the force of the water when pouring it on plants without the use of the rose.

1416. *The Italian watering-pot* is formed of earthenware in shapes similar to the French.

1417. *The watering-tube* (fig. 184.) is a tin tube with a funnel joined to it at right angles at one end, and with or without a rose joined to it in an opposite direction at the other. It is used for watering pines, and other potted plants in pits or beds, not easily reached, and where it is desirable not to moisten the leaves.

1418. *The garden-syringe* is of different species: the common is made of tinned iron, copper, or brass, generally about two feet in length, and two inches in diameter.

1419. *Read’s syringe* (fig. 185.) is by far the best implement of the kind. By means of a ball valve (d), which can never go out of repair, the water is drawn in through a large opening, and forced out either through a fine rose (e), a larger rose (b), or in one spout (a), each forming a separate cap, which screws off and on. In common syringes the air above the piston proves an obstacle to the operation of the syringe, and greatly increases the labor of the operator; but in Read’s syringe there is a tube (f) by which this air escapes in the operation of drawing in water, and the space is as readily replaced with air through the same aperture in pressing the water out again. It is
astonishing how much this lessens the power requisite either to fill the syringe or empty it. A child may do with Read’s engine, what requires a man in the common kind. This instrument may be considered as superseding not only the common hand-syringes, but even the barrow-engine, and other machines of this kind to which the same improvements are not applied.

SUBSECT. 3. Utensils of Protection.

1420. Utensils of shade, shelter, and exclusion are the cover, shade, blancher, hand-glass, and bell-glass.

1421. Plant-covers are of different species.

1422. The portable cloth cover or shelter is of different species: it consists of a frame of wicker-work, of any size, from that of a hand-glass, to six or eight feet high, which is covered with gauze, oiled canvas, matting, and sometimes entirely with wicker-work. It is used for protecting half-hardy shrubs and plants in the winter season, and when recently transplanted.

1423. The portable paper cover or shelter is a small frame, like the skeleton of a hand-glass, covered with oil-paper, and is used for protecting cauliflower-plants, striking cuttings, &c.

1424. Shades are of three species. The place-umbrella (fig. 186.) resembles the domestic instrument of that name; but instead of the ordinary handle, has a pointed rod, shod with iron, for insertion in the ground. It is used for shading tender plants from the sun, or sheltering them from the rain. For both purposes it is convenient to have a joint in the stem, so as to incline the cover according to the situation of the sun and the direction of the rain. They are much used in the Paris garden, and at Monza, in Lombardy.

1425. The portable wire shade is a bottomless cage of wire or wicker work, to place over tender plants, to protect them from excess of wind, sun, and rain. They are a good deal used in the botanic gardens of the continent, for moderating the direct influence of the sun on plants of cold climates.

1426. The earthenware shade (figs. 187, & 188.) is in the form of a flower-pot, but with a section cut from one side to admit the air and light. This open side in the case of auriculas and Alpine plants, is placed to the north, and in the case of tender plants to the south, or other points. These utensils are exceedingly useful in transplanting tender plants, and in cultivating Alpine plants. One species (fig. 188.) is entirely perforated with holes, for shading ferns, mosses, and fungi. Common pots are often used for sheltering and shading newly transplanted articles with the greatest benefit.

1427. Blanchers are any close utensil that when whelmed over a plant will exclude the light. The most common is the blanching-pot, which is used to exclude light from secalce and rhubarb-stalks, and some other culinary vegetables, where the green color is to be avoided. In the Pyrenees they are used for blanching celery.

1428. The conic blanching-pot is in the form of a sugar-loaf, and is used in France for blanching lettuce and endive. (Lasteprie.) In Valentia, asparagus is blanched stalk by stalk, by portions of reed with a knot or joint placed over each. (Ibid.)

1429. The hand-glass is of various species.

The leaden hand-glass is a small portable glazed case, formed by grooved strips of lead, and is either square or polygonal in the plan and roof. It is used for the protection of culinary and other plants, during the winter months; its first cost is less than that of any other hand-glass.

The copper hand-glass (fig. 183) is a very light and elegant variety of hand-glass, in which the bars are formed of copper, the sides bevelled, and the top or roof sometimes projects over the latter, with glass eaves. The lead hand-glass is the cheapest, but this is by far the most elegant; they are manufactured by Jorden, and others, in Birmingham, and constitute one of the most elegant utensils used in gardening.

The cast-iron hand-glass (fig. 190) consists of two parts, the sides either square or polygonal, and the top of suitable shape. Each side is cast separate, with screws and nuts; the four sides are afterwards
screwed together, and the top, which is always kept separable is cast in one piece. When air is to be given to the plants enclosed, it is done by lifting up the top, and replacing it diagonally, by which means air is admitted in every direction; and one advantage of not being obliged to lift the bottom part is, that in severe weather, when it is frozen to the ground, air is admitted without danger of breaking the glass; and also that the leaves of large plants, as of cauliflower, are less liable to be injured in replacing it. A glass case may be composed from two or three of these hand-glasses, of any height, by placing two or three bottom frames one above the other. The relative prices, the size and shape being the same, is in the order of lead, copper, and cast-iron.

1430. The wrought-iron hand-glass (figs. 191, & 192) is composed of solid iron sash-bars, and may therefore be formed of any shape or height. It is particularly eligible for covering tender shrubs, fixed in the open air, as tree-peonies, some half-hardy mimosas, &c., and even geraniums and fuchsias in the south of England.

1431. The bell-glass differs from the hand-glass in being one entire piece of glass and commonly bell-shaped, semi-globular, or cylindrical.

1432. The common green glass bell (fig. 193) is formed of bottle glass, and is commonly used in the open garden for protecting cauliflowers or other culinary plants, or for striking cuttings or retaining a moist atmosphere about seeds, &c.

1433. The crystal bell or receiver, (figs. 194, 195, & 196) used in gardening, is generally from three to eight inches in diameter, and from four inches to one foot in height; they are employed in striking tender cuttings in the exotic departments, especially heaths.

1434. The essential utensils are the sieve, flower-pot, watering-pot, and hand-glass.

**Subsect. 4. Utensils for entraping Vermin.**

1435. Bird, beetle, and wasp traps constitute the only genera of this tribe of the class worth mentioning.

1436. The birdtrap-cage (fig. 197.) is a wicker utensil with a funnel, through which the bird having descended in quest of the bait placed within, cannot ascend. It is successfully employed to catch young sparrows.

1437. The earwig and beetle trap (fig. 198.) is often only a hollow cylinder, but from this, if not taken regularly at certain seasons, the insects escape. A close box, with an inverted truncated cone of glass in the centre as a hopper, is better; because when earwigs, beetles, wood-lice, or such insects enter, they cannot escape, and may be drowned or scalded, or suffered to die there. The common bait is crumbs of bread.

1438. The wasp and fly trap, is merely a bottle half full of water honied at the mouth to entice their entrance. Some assert that the plant hoya carnosa, whilst in bloom, will attract wasps and all other insects from the fruit in the house in which it grows (Maher, in Hort. Trans. vol. i. 197.); and others that boiled carrots will have the same effect.

**Sect. IV. Machines.**

1439. Machines are agents for abridging manual labor. All the operations of gardening may be performed by the simple tools, instruments, or utensils, already mentioned; but in practice some labors would be insufferably tedious, and others inconveniently cumbersome; and in many operations, the ordinary force of man could not be conveniently brought into action. Rollers, as opposed to the turf-beetle, are illustrative of the first case; the German devil, and Bramah's hydrostatic press, as opposed to a number of men with ropes or levers, of the second; and the boat-scythe, as performing the operations of the pickers or common scythe, of the third case. But the machines of gardening are very few, and chiefly artificial contrivances for the defence of gardens or scientific machines for measurement or designation of temperature. In contriving either
of these, simplicity ought to be attended to; for a complicated machine is not only more expensive, and more apt to be out of order, but there is also a greater degree of friction, according to the number of rubbing parts.

**Subsect. 1. Machines of Labor.**

1440. *The more cumbrous machines of gardening are the barrow, roller, watering-engine, boat-scythe, ladder engine, and transplanter.*

1441. *Garden-wheelbarrows are of several species. The common garden-wheelbarrow* (fig. 199.) *is a box, open at top, placed on two levers, terminating in a wheel and axle at one end, and in two handles at the other. They are commonly made of wood, the levers of ash or elm, and the sides and bottom of any soft wood. The wheel is either wholly of cast-iron, or of wood, shod with wrought-iron. Excellent garden-wheelbarrows are now made of wrought-iron; but wooden ones are better for new ground work. They are used for conveying dung, weeds, garden-soils, litter, &c.*

1442. *The separating barrow is, in appearance, the same as the above, but the body being kept in its place by two iron bolts at opposite angles of the bottom, may be lifted off by two men, and thus tan, dung, and other articles are readily carried into hot-houses, where the wheel and levers could not be pushed along.*

1443. *The new ground work barrow* (fig. 200.) *differs from the first in having the sides and back very low, and a front of the same height. It is made much stronger, and is used chiefly for wheeling earth, clay, or gravel, in extensive excavations or removals of these materials.*

1444. *The haulm-barrow* (fig. 201.) *is an open box or case of wicker or other work placed on or suspended from a pair of handles, with or without a wheel, and is useful for carrying litter, leaves, haulm, spray, prunings of hedges, &c.*

1445. *The flower-pot barrow* is a flat surface and wheel, on which plants, pots, or leaves are placed either directly, or when small in one or more shallow baskets.

1446. *The water-barrow,* instead of a box, contains a barrel, tub, or cistern, in which fluid manure or mere water is conveyed to different parts of the garden.

1447. *The hand-barrow* is a frame of wood carried by two levers, which form four handles, and is used, in gardening, for removing large pots or tubs of trees in blossom or in fruit, and which wheeling might shake and otherwise injure.

1448. *Watering-engines are of several species.*

1449. *The pump-syringe, or hand forcing-pump* (fig. 202.) *consists of a barrel-piston and directing-tube. The water is drawn up through a perforated base; and the advantage of this engine is, that it may be placed in any common watering-pot or bucket, and thus much room and some trouble and expense saved in small gardens.*

1450. *The barrow watering-engine* (fig. 203.) *is a portable forcing-pump so arranged as to throw the water forty or fifty feet distance, and either in the form of a spout or a fine shower. The cistern commonly contains from twenty to thirty gallons of water, and the frame which holds it being fitted up as a wheelbarrow, it may be wheeled round the garden, and the walks, borders, or even the compartments to the extent of forty-five feet from the walk may be watered completely. The most desirable variety of this machine
is that which is furnished with a sucking-pipe (a), like the fire-engines, by means of which, if there are ponds or regular supplies by pipes or wells in a garden, the labor of carrying the water is avoided.

1451. The curved-barrel engine (fig. 204.) has the barrel and piston-rods curved so as to form part of a circle, &c. By this construction, the bore of the barrels may be formed in the lathe, and consequently made perfectly true: the piston-rods move exactly in the direction of the axis of the barrels, and therefore operate with the least possible friction. For a portable engine this is one of the best. — Both these engines would receive great additional power, by adopting the improvements on the syringe by Read. (1419.)

1452. The self-acting greenhouse-engine is a small vessel of cast-iron, one part of which is filled with air, highly condensed by a piston, and the other with water, which, by turning the cock, is let out by a spout either as a shower or stream. The machine may be held in the hand, and the stream or shower directed against any particular plant. Instead of water, if tobacco-smoke is introduced, the smoke will be driven with great force to a considerable distance. This machine will throw the water from thirty to fifty feet, but its chief use is in green-houses, for the purposes of fumigation, as a plant on the upper part of a stage may thus be fumigated without touching it, or the operator being nearer it than the path. On the whole, it is more an instrument for the amateur than the practical gardener.

1453. The carriage water-barrel is used for watering lawns the first season after their formation, when the weather is dry; or for watering borders or other cultivated surfaces near a broad wall. In the former case, the water is delivered by a horizontal tube six or eight feet long, perforated at the lower angle so as to produce a series of horizontal jets; in the latter, a long leathern tube, terminating in a rose, is made use of. The barrel in the first case is drawn slowly along by a horse, in the latter it is nearly stationary, and a man waters on each side as far as may be deemed advisable, or as the leathern tube admits.

1454. The roller water-engine (fig. 205.) consists of a horse, frame, and wheels, on which is placed a water-barrel, and under it an iron roller. It is an excellent machine for lawns and roads, as they may be watered and rolled by the same operation. The person who directs the water, irrigating the space to be rolled, not that which has undergone the operation.

1455. The garden-roller is formed either of wood, stone, or cast-iron. The first requires to be loaded; the second, from the smallness of its diameter, is heavy to draw; and therefore the third, which may be formed of any diameter, weight, or breadth, is generally preferred for garden-walks. The cylinder need not be above four feet wide, which will cover most walks at two or three breadths. For extensive lawns the horse-roller will be preferred.
1456. Garden-ladders are of three species.

1457. The common wall-tree ladder differs from those used in other arts in having two pieces of ten or twelve inches in length, projecting at right angles from the upper end, the use of which is to avoid injuring the trees, by keeping the top of the ladder at a small distance from the wall, and thus admit of the operation of nailing, as well there as elsewhere.

1458. The orchard-ladder consists of a frame on low wheels, as a basis for several ladders which fit into each other, and are capable of being hoisted up by machinery so as a person near the extremity of the ladder may have access to any part of a tree with convenience, either to prune it or gather the fruit.

1459. The three-styled, forked, and double ladders (fig. 206. a, b, c) are also well adapted for the ordinary purposes of gathering fruit or pruning.

206

1460. The rule-joint ladder (fig. 207.) is used for working on curvilinear roofs either of glass, or domes of lead, stone, &c. which require panes renewed or trees nailed. Each step or foot-board, has what is called a stop, to prevent the feet from breaking the glass, and at every joint is a moveable foot to project in the case of training trees on such surfaces, in order that their leaves, &c. may not be injured. Such ladders are particularly useful for repairing curvilinear hot-house roofs.

207

1461. The step-ladder (fig. 208.), instead of round rods on which to place the feet, has steps or boards, an improvement essentially necessary, where much work is to be done, because less fatiguing to the feet. Such ladders have a back or fulcrum by which they stand independently of any other object, and which is removable at pleasure by drawing out an iron bolt.
1462. The platform is of two species.
1463. The portable platform combines a step-ladder and platform, which in part comes to pieces, and in part folds together, so as readily to be carried from place to place, and to occupy little room in a tool-house.
1464. The wheel-platform (fig. 209.) is a flat surface of boards generally five or six feet square, elevated by a frame with wheels; it can thus be moved along lawns or walks, and is used chiefly in clipping lofty hedges. A variety of this, used in some places, has folding steps or boards on two sides, supported by brackets, by which three men at different heights, and one on the ground, can proceed with dressing the whole side of a hedge at once. Such a machine is used in shearing the magnificent hornbeam hedges in the imperial gardens at Schoenbrunn, and those of spruce fir at Petrowsky, near Moscow.
1465. The boat-scythe, for mowing weeds in ponds, is a machine invented by General Betancourt, now of Petersburgh, consisting of a boat with a system of wheels and pinions placed in the head, which give motion to a vertical shaft, containing on its lower end (which passes through the bottom of the boat into the water) three scythes; two men communicate motion to the machinery, and one man rows the boat; the upright shafts on which the scythes are placed, can be raised or lowered according to the depth of the weeds, &c. This machine has been improved by General Betancourt, but is capable of being further simplified.
1466. The garden sharpening-engine is of several sorts.
1467. The grindstone, as well as whetstone, scythestone, hone for penknives, (the last used in making cuttings of heath and such like plants,) are necessary in every garden. Blunt spades, hoes, or knives should never be used, as they cannot operate properly in the hands of the most expert gardener.
1468. Tree-transplanting machines of two or more species have been invented. The pole and wheels (fig. 210.) is for general purposes the best of any of them. It consists of a long beam or pole, attached to an axle and wheels. The tree being prepared for removal, and the pole placed in a vertical position against it, the stem or trunk is attached to it by ropes; thus attached, they are brought into a horizontal position, by men or horses, with the ball of earth attached to the tree. Horses may then be yoked to the axle at the opposite end of the pole, or root end of the tree, with or without the aid of another axle, and the tree drawn to any distance and planted. In favorable climates, and when a little extra expense is no object, astonishing effects may be produced by removing large trees; and no machine is better adapted for aiding in the labor than this simple union of the pole and cart-axle.
1469. The German devil is a frame of timber, with a cylinder moved by a combination of wheels, and a winch, as in raising clay or earth from pits or mines by manual labor. But instead of the bucket of clay, three hooks are attached to the end of the lifting rope, and these are fastened to the roots. (See Hunter’s Evelyn’s Sylva.)
1470. The hydrostatic press (fig. 211.) may be applied to the same purpose as the German devil, with incomparably greater effect. The only difficulty is in finding a proper and convenient fulcrum; that done, this engine will root out the largest trees. It is successfully employed by engineers in drawing piles, gate-posts, raising stones, &c. (See Nicholson’s Arch. Dict. art. Hydrostatic Press.)
1471. The garden-seed separator is a small portable threshing machine, on Meikle’s principle, but fed, in Lee’s manner, from a hopper, and with a winnowing machine either under or connected with it. (fig. 283.)
1472. The essential machines of garden-labor may be considered the wheelbarrow, roller, and hand forcing-pump.
Subsect. 2. Machines for Vermin, and Defence against the Enemies of Gardens.

1473. Of engines for entraping or destroying vermin, and for the defence of gardens, there are but a few. All of them, with their modes of operating, are referable to commonly understood mechanical and chemical principles, and to certain instincts and propensities of animated beings, which it is unnecessary to detail.

1474. Engine-traps for man are of two species, the common and the humane.

1475. The common man-trap is a rat-trap on a large scale, differing from it only in the mode of setting; the former being baited and left loose, and the latter not being baited, but fixed to the ground by a chain. This is a barbarous contrivance, though rendered absolutely necessary in the exposed gardens around great towns. Its defect is, that its severity defeats its own purpose; for though kept and exposed to view in many places in the day-time, yet few venture to set them at night, and hence intruders, calculating on this humanity, enter and commit their depredations in spite of these machines.

1476. The humane man-trap, instead of breaking the leg by crushing, and consequently by the worst of all descriptions of compound fractures, simply breaks the leg, and therefore is comparatively entitled to the appellation of humane. It is not unfrequently set in market-gardens near the metropolis.

1477. Engine-traps for quadrupeds are chiefly the mouse, rat, and mole traps.

1478. The garden mouse-trap is generally composed of a slate and a brick, supported by a combination of three slips of wood, forming the figure 4, and baited by a pea or bean. A few cats domiciled in the back sheds of hot-houses, will generally keep a walled garden clear of this enemy; but the above trap is good for open grounds.

1479. The garden rat-trap (fig. 212.) should generally be a box, or enticing engine, of some sort, rather than a toothed iron trap; because unless there is a great scarcity of food, which is seldom the case as to the field rat, it will not be allured by the bait of the former; whereas a trap may be so disguised by straw, or moss, or leaves, and so scented by oil of anise, as to be resorted to or at least not recognised by the rats till they are taken.

1480. The mole-trap (figs. 213, & 214.) is of various forms, and either made of wood or iron, or of both materials. There are several varieties to be obtained in the shops; none of which appear superior to the original bow-trap, which any laborer may form for himself. Moles may be effectually destroyed by taking their nests in spring.

1481. Engines of destruction are the spring-gun, musket, and fumigating bellows: the musket is essentially necessary, both as a destroyer, and scare of birds.

1482. The fumigating bellows (fig. 215.) differs from the common domestic bellows in having a receptacle (a) for leaves of damaged foreign or of home-grown tobacco, which being ignited, and the blast sent through it, a powerful issue of smoke is produced by the rose (b), which can either be directed against insects on particular plants, or used to fill the atmosphere of a hand-glass, frame, or hot-house.

1483. Engines of alarm, or scares, are the bell or gong alarm for man; and the rattle-engine driven by hand, or a small wind-engine for herds.

1484. The concealed alarm is a system of wires spread over a garden or orchard, like those of the spring-gun, and terminating in a bell or gong alarm, which goes off when any of the wires are disturbed. This alarm may be in or near to the gardener’s room, watch-tower, or other suitable place, though at a considerable distance from the wires. This is, perhaps, on the whole, the best way of detecting intruders. In addition to setting off an alarm, the same wire may let loose a watch-dog, drop a heavy body, or a fulminating glass bead, discharge a gun, &c.

1485. Of living vermin-killers, the ferret is useful for catching rabbits, squirrels, and ground rats; the cat for mice, rats, and birds; the terrier for eradicating foxes; and ducks and gulls eat snails, worms, frogs, &c.

1486. The essential vermin-engines are the mole and mouse traps, fumigating bellows, and musket.
1487. *The garden-indicators of weather* differ from those in common use only in two instances, that of the registering thermometer and regulating thermometer. *The barometer, hygrometer, rain-gauge, and vane or Eolian index, may all be usefully employed in gardening, (1278,) and should be fitted up in and about the gardener’s office. The rain-gauge and vane may be placed on the roof of his office, and should communicate with the interior by means of tubes and machinry, the detail of which is perfectly known to opticians, and such as fit up apparatus of this kind.

1488. *Six’s registering thermometer (fig. 216.) is so contrived as to indicate the extreme points to which it falls or rises in the course of the day or night, and is, therefore, particularly useful as a check upon the working gardeners, who have to attend to the fires, or steam, &c. of hot-houses in the winter time. In the open air it is also a very useful instrument, by pointing out the extremes of temperature. (Nich. Encyc. art. Thermometer.*)
1489. Kewley’s alarum-thermometer (fig. 217.) consists of a glass tube \((a, a)\), about ten inches in length, hermetically sealed at one end, and united at the other to a capillary tube \((b, b)\), with an intervening and also a terminating ball \((c)\) and \((d)\). Imagine this double tube placed in a horizontal position, the largest tube, and half the intervening ball, filled with spirits of wine; and the smaller tube and half of both of the balls, with mercury. If the tube is now fixed by its centre in a brass frame \((e)\), and nicely balanced, it is evident that every change in the temperature of the atmosphere will produce a change in the position of the centre of gravity of the tubes. One degree of heat, by expanding the spirit, will press on the mercury in the intervening ball \((c)\), and drive part of it over to the terminating tube \((d)\), which end will, in consequence, descend like the beam of a pair of scales or of a steam-engine. Hence a moving power of great nicety and certainty is obtained, the details for the application of which, to the ringing of a bell at any distance, communicating by a wire \((f)\), need not be here entered into. Suffice it to say, that by means of a scale \((g)\), it may be set to any required temperature, and will give the alarm at a difference of even the fourth of a degree, either of depression or elevation. It may be occasionally used in gardening, to convey some idea of the changes taking place in the temperature of particular hot-houses, to the head gardener’s room, in the night-time; but its most important uses are in domestic economy, hospitals, &c. This balance-thermometer, as it may be called, has been also applied, by its ingenious inventor, to the opening and shutting of windows or sashes, valves of chimneys, or flues. and steam-cocks, and either to all of these purposes at once, or to any one of them.

1490. Kewley’s regulating thermometer, or automaton gardener (fig. 217.), consists of a particular application of the alarum thermometer just described. For this purpose, the thermometer is made from two to three feet in length, and the same principle may be extended to any length, as ten or twelve feet, with a proportionate increase in the diameter. The apparatus which Kewley applies to the thermometer, and which enables him to get the power requisite for opening the sashes or windows of hot-houses or buildings of any magnitude, is a metal cylinder \((k)\), generally of rolled copper, as being cheapest, from seven to fourteen inches in diameter, and from eighteen inches to two feet in length, with an accurately fitted piston \((j)\). This cylinder is placed either within or without the hot-house or room in any convenient situation, and a cistern, or a barrel of ordinary dimensions, filled with water, is placed on an elevated situation, say on a level with the chimney-top. The deeper the cylinder is sunk, the less the cistern requires to be raised above the level of the floor of the house. If, as is often the case, a pipe of water is conducted through the house from a distant reservoir of ordinary elevation, then nothing more is necessary than attaching a branch-pipe. It is requisite that this pipe pass directly to the point where the thermometer is placed, and at any convenient distance under it, not higher than the bottom of the cylinder. Here it is joined to a tripartition cock \((k)\), whence proceed two other pipes, one \((l)\) to the cylinder, and the other \((m)\) to a waste drain. The stopper to this cock turns only to the extent of about one-fifth of a circle; and when turned to this extent to the right, it opens a communication between the supply-pipe \((n)\), and the cylinder \((b)\), when the pressure of the water in the reservoir, whether a barrel on the top of a house or a distant cistern, raises the piston, and by a communication of cords and pulleys with the sashes \((o)\), they will be raised or opened; and by another chain \((p)\), the fire or steam-damper \((q)\), will be opened also. When the cock is turned to the left, this communication is stopped, and one opened between the cylinder and waste-pipe \((m)\), by which the water escaping, the piston descends, and the sashes and dampers are shut. The equilibrium of the balance-thermometer restored by the temperature, being reduced or elevated to the proper degree, the plug is neither turned to the right nor left, and every communication is closed. The cock is worked by two wires \((r, r)\), fastened to two short levers, fixed on each side of the thermometer-frame, and the other ends of the cross or handle of the cock \((s, s)\). To set the machine at work, it is only necessary to place the scale to a degree at which it is desirable air should be given, taking care that the cistern is not without water. A small cask of water, regularly supplied, will answer as well as a large cistern, as the power is not as the body of water, but as its height. As a hot-house seldom remains many minutes at the same degree of heat in the day-time, it is evident that the sashes would be in almost continual motion, which, in houses where the sashes open outwards, and especially the polypusropic, to be afterwards described, would have a singular and animated effect in a flower-garden, or on a lawn. Where light valves or ventilators are used, the balance-thermometer of this size has sufficient power to open them without the aid of machinery; and by lengthening the tube, sufficient power may be obtained to open balanced windows in dwelling-houses, churches, or hospitals. This machine was originally contrived for the use of the inventor’s own garden in Douglas (Isle of Man), and successfully employed to give air to pits and frames there for two seasons. Having come to London, he employed it with the addition of more machinery (see the patent, 1816) than he now uses, to ventilate a part of a house in the New Kent Road, from 1816 to 1817. In 1818 he greatly simplified it, and thus im-
proved, it was in operation on a hot-house in Colville's nursery, King's-road, during the summer of 1819. In both cases the success was perfect and undisputed. The price of the alarum-thermometer is from two to three guineas; and of the regulator, from six to ten pounds complete. These machines were exhibited to Sir Joseph Banks and to the Horticultural Society. But the president and other individuals of this body thought such a machine not wanted in gardening. We cannot but regret, however, that some mark of approbation was not bestowed on the author of so ingenious an attempt to render a service to our art, and who, like other inventors, had devoted a great part of his time, and the greater part of his fortune, to bringing the invention to its present state. We are glad to see that it has been noticed by the Caledonian Horticultural Society (Mem. vol. iii. p. 170.), and we trust the inventor may yet obtain, at least, credit for his genius in mechanics.

Sect. V. Various Articles used in Gardening Operations.

1491. The objects used in gardening, which can neither be denominated implements nor machines, may be classed as adapted articles, manufactured articles, and prepared articles.

Subsect. 1. Articles of Adaptation.

1492. Of articles fitted for particular situations or objects, we shall notice the temporary coping, horizontal shelter, moveable edgings, basket-edgings, and a few others.

1493. The temporary coping is commonly a board, or two or more boards joined, so as to form a breadth of eighteen inches or two feet. To these boards hinges are attached, which fit into irons on the front upper edge of the permanent coping of the wall; and thus, by means of a rod or a cord and pulley, the board is either made to project over the front of the wall, or is laid flat on the top of the permanent coping.

1494. The horizontal shelter is a board of eighteen inches broad, and of any convenient length. By means of iron pins inserted in the wall, a number of such are placed horizontally, like shelves, about the middle and top of fruit-walls, to protect the blossom from perpendicular colds and frosts; they were first recommended by Lawrence, but are now seldom used.

1495. The netting screen (fig. 218.) consists of two deal poles, on which is nailed a common fishing-net previously dipped in a tanner's bark-pit, to prevent its being mildewed when rolled up wet. At the top, the ends of the poles fit into double iron loops, projecting a few inches from the wall, immediately under the coping; and at the bottom they are fixed by a hole at the end of each pole upon a forked iron coupling, which projects about fourteen inches from the wall, thereby giving the screen a sufficient inclination to clear the branches. When it is wished to uncover the trees, one of the poles is disengaged and rolled back to the side of the other, where it is fastened as before. The most violent winds have no injurious effects upon shades of this kind; a wall is very expeditiously covered and uncovered, and there is not any danger of damaging the blossoms in using them; they occupy very little space when rolled up, are not liable to be out of order, and although rather expensive at first, seem to be very durable. From the facility with which the screen is put up, it may be beneficially used in the seasons when fruit ripens, to secure a succession, by retarding the crop of any particular tree. The lower ends of the poles are advantageously retained in their places, by means of a small iron spring-key attached to the coupling by a short chain." (Hort. Trans. vol. iv.) Canvass, oil-cloth, or gauze screens, may be similarly formed and fixed.

1496. The canvass screen is a sheet of canvass in a moveable frame, to be placed against blossoming wall-trees during nights, and removed during temperate weather. Bunting, rendered more transparent by oiling, is considered by Nicol as preferable to canvass. Others recommend Osnaburgh or Scotch gauze. The screens should have hooks, to hook into projecting eyes at the top of the wall, from which, as well as at bottom, they should be kept distant one or two feet. "Canvass screens in frames may be fitted to move in the manner of a common sash, between rafters, and may be double, as in a
window, to go either up or down, in order to admit air. The rafters being made move-
able, by being fixed with hooks to stretchers at top and bottom, the whole could easily be
removed or replaced at pleasure. Thus a frame might be made of ten, fifteen, twenty, or
more feet in length, to answer for one or more trees, as may be required; and if the
whole be packed and laid up in a dry loft, garret, or shed, each season after using, it may
last for many years." (Nicol.)

1497. The canvas curtain is so arranged by means of pulleys and weights, as to be drawn
up over a wall of a hundred feet in length in a few seconds, and let down and spread
out to dry in a short time. It is kept at a distance from the trees by cords stretched
from the coping to the ground in a sloping direction: a fine example of this occurs at
Dalmeny Park garden, near Edinburgh, erected under the inspection of J. Hay of
Edinburgh, a meritorious designer of kitchen-gardens. "If screens be made in sheets,
Nicol observes, "they are best to hoist up and lower with pulleys and cords (which
pulleys may be fixed to the coping, as above mentioned, or to a beam or stretcher fixed
at the top of the wall), they should be suspended over small rafters or spars, of an inch
and a half to two inches square, according to their lengths, placed so closely as to pre-
vent the canvas from dashing against the trees, as above hinted. Sheets of this kind may
be of any convenient size, and made to cover one or more trees, as may be required.
I have had one sheet 200 feet in length, which I could join or unjoin at two or three
different places, and could unclewed and hoist, or lower and clew up, in fifteen or twenty
minutes. I first contrived it to clew at the top of the wall, but afterwards found it
safer to do it at bottom, as a gust of wind had once nearly torn it away altogether. In
the clew it was hung by loops to the bottom part of the upright spars (which were placed
at four feet asunder), so as to be a few inches clear of the ground. These rafters were
fastened with hooks and eyes to the coping at top; and at bottom to stakes drove fast
into the earth, eighteen inches clear of the wall." (Kalendar.)

1498. The oiled-paper frame consists of a light frame of timber, with cross bars mort-
tised into the sides, and intersected by packthread, forming meshes about nine inches
square. Common printing-paper is then pasted on, and, when quite dry, painted over
with boiled linseed-oil. These frames are then fitted to the wall, or subject of protection,
according to circumstances.

1499. The garden-hurdle is of different species.

Wire hurdles are used as inconspicuous fences, and sometimes for training plants or young hedges.

Wattled hurdles, or such as are woven with sheets or spray, for shelter and shade.

Straw and reed hurdles are used for shelter, for shade, and for covering frames and other plant-habitation,
or for forming temporary cases around plants to exclude cold.

1500. Moveable edgings to borders, beds, or patches of flowers, are of different species.

1501. The basket-edging (fig. 219.) is a rim or fret of iron,
wire, and sometimes of laths;
formed, when small, in entire
pieces, and when large, in seg-
ments. Its use is to enclose dug
spots on lawns, so that when the
flowers and shrubs cover the
surface, they appear to grow
from, or give some allusion to,
a basket. These articles are also formed in cast-iron, and used as edgings to beds and
plots, in plant-stoves and conservatories.

1502. The earthenware border (fig. 220.) is composed of long narrow plates of com-
mon tile-clay, with the upper edge cut into such shapes as may be deemed ornamental.
They form neat and permanent edgings to parterres; and are used more especially in
Holland, as casings, or borderings to beds of florists' flowers.

1503. Edgings of various sorts are formed of wire, basket-willows, laths, boards, plate-
iron, and cast-iron; the last is much the best material.

1504. Protecting bags, for guarding ripening fruits from insects, are formed of gauze,
oiled-paper, or muslin-paper; gauze is preferable, as it admits the air. They are used
with advantage, in the case of grapes and stone-fruit, on walls in the open air, and in
some cases are required even in hot-houses.

1505. The shoe-scraper is a plate of iron, fixed vertically, either in a portable or fixed
frame; and to render it complete, should always have a rigid brush and dust-box at-
thached, both of which may be taken out and cleaned; their use in gardening is consid-
erable, portable ones being placed at the entrances to every description of garden-
building, and fixed ones at the exits from compartments to the main walks. They ought
to abound, and their use be effectually insisted on wherever clean and pure gravel or turf-
walks are desired objects.

1506. Garden or bass mats, are sheets of cloth, woven or matted from the bast (Russ.)
or inner bark of trees, and generally of the lime. They are manufactured in the inland parts of Russia and Sweden, and even in some parts of Monmouthshire, of different sizes. They are used in gardening for a great variety of purposes; for protecting wall-trees, by being hung before them, and removed in mild weather; for protecting espaliers and standards, by being thrown over them; for protecting more delicate shrubs, by being thrown over an envelope of hay or straw, in which way most American trees and standard-roses are protected in the neighbourhood of Petersburg; for protecting tender-plants coming through the ground, by being spread on its surface, and such as are of a larger size, by being supported on hooped framing. They are used to cover hot-beds, hot-houses, hand-glasses, and every sort of glass case; to shelter plants from wind, shade them from the sun, &c.

1507. Prepared coverings are double mats with a layer of hay or straw within, like mattresses; they are used for covering hot-beds in mid-winter, but are readily rendered injurious by heavy rains. A mode which would produce the same effect, is to use three thicknesses of mats, keeping them apart by small frames of lath or hollow rollers; the object being to preserve vacuities or strata of air between the glass and first mat, between the first and second mat, and between the second and third mat, which, if attended to, would resist any external cold whatever without cumbersome loads of hay, straw, &c. (See Dr. Wells on Dew, and Remarks on Hot-houses, &c.)

1508. Straw coverings are formed of straight long wheat or rye straw, tied in handfuls in the middle, so as each handful may be nearly of the length of two straws, and the handfuls are connected together by backthread. They are thus formed into rolls, and were formerly much used, especially in the culture of early salading, and in covering glass cases. Melons were formerly protected by nothing more than loose wheat-straw, and this mode by rolls seems merely a more economical and neat mode of practice. Loose wheat-straw is used by the market-gardeners, to protect early crops of radishes and other saladings.

1509. Reed coverings are formed exactly like those of straw, and are used chiefly for protecting glass, or forming protecting cones round tender shrubs, or bee-hives of the common kind.

Subsect. 2. Articles of Manufacture.

1510. The manufactured articles used in gardening are chiefly canvass, gauze, netting, mats, and nails.

1511. Canvass, either plain, oiled, tanned, or painted, is used for protecting the blossoms of wall-trees; excluding cold from plants or plant-structures, shading or sheltering plants, and for keeping off rain.

1512. Coarse gauze and netting, such as is used by fishers and bird-catchers, may be prepared similarly to canvass, and used for the same purposes as that article, excepting excluding rain. Oiling or tanning is best adapted for gauze; as painting or tarring destroys its property of transmitting light.

1513. A netting of straw ropes has been found efficacious in protecting trees from frost, either thrown over an entire standard-tree, or hung before fruit-walls. They are used at Dalkeith gardens, near Edinburgh, and were formerly much resorted to in the Netherlands.

1514. Wall-tree nails are of several sorts, but the principal are, the small cast-iron nail, in most common use with lists; the flat-headed wrought-iron nail, used either with lists, loops of cord, or mat; and the eyed cast-iron nail (fig. 221.), used with small pieces of spray, dried willow-twigs, or mat-ties, as in trellis-training. Its chief advantage is the not being so liable to lodge the larvae of insects as the nails which are used with lists; and being once driven, they never require removal, or occasion the injury of the wall, as the branches may be loosened, or altered, by merely taking out the slips of spray, or cutting the mat-ties. (Caled. Mem. vol. iii.)

1515. Wall-tree lists are marginal ends or shreds of broad cloth cut into lengths of from two and a half to four inches, and from one half to one inch in breadth, according to the size of the shoots, &c. Their grand disadvantage is the harboring of insects, for which some have substituted shreds of leather with advantage, and others recommend steeping the shreds in a mixture of sulphur and soap-suds, or better in that of corrosive sublimate, recommended for preserving specimens of plants. (581.) The colors of black, scarlet, and reddish-brown are the best for lists, as contrasting well with vegetation.

Subsect. 3. Articles of Preparation.

1516. The prepared materials used in gardening are numerous: we shall merely enumerate props, ties, covering materials, gravel, sand, cinders, lime and straw.

1517. Props for plants are of two kinds, rods or poles, and spray. Rods vary from six inches to six feet or upwards in length, tapering to a point, and thick in proportion. For small plants in pots, and for delicate bulbous roots, as hyacinths, small splinters of lath, dressed with a knife or small plane, are the best; and for hyacinths and florists' flowers in general, they should be painted green; for botanical plants, however, this may, in some cases, appear too formal. For hardy plants and climbing shrubs, young shoots or poles of hazel or ash from coppice-woods are the most suitable; they should
in general, be straight and tapering to a point, and as delicate as the weight of the plant, and the exposure of the situation will admit. The side shoots of these props should, in most cases, be cut off; but in others, as in propping the dahlias, it is desirable to have some lateral studs, from three to eight inches long, near the top, so as to spread out the head. In lieu of this, several props are sometimes used, placed in form of an inverted pyramid, or cone, or a regular prism. One prop, however, judiciously managed, will generally be found sufficient. In no case should the bark be removed, because its natural tint is less glaring, and therefore preferable to that of peeled wood, and also because it preserves better the texture of the wood. In order that they may last several years, they should be cut in mid-winter, and the thick end pointed and charred by burning, or dipped in boiling pitch. The elegant propping of plants deserves the particular attention of the young gardener, as it is frequently done in so slovenly a manner as greatly to detract from the order and neatness which ought to reign in most descriptions of gardens. In picturesque grounds or picturesque scenes, trees and shrubs should, in general, prop themselves, or each other; but in flower and botanic-gardens, flower-borders, green-houses, &c. the greatest degree of art and high-keeping, and a sort of *drilled polish*, easier felt than described, ought always to prevail. In all that respects this part of gardening, the French and Germans greatly excel the English, who are herein too apt to look at the end, without regarding the means.

1518. Spray or branches are used as props for plants furnished with tendrils, as the common pea, and many of the leguminous tribe. Spreading frond-like, and yet thin spray, such as that of the beech, hazel, or Scotch elm, is generally preferable; but for early crops the spray of the resinous tribe, and especially of the spruce and silver firs, is valuable, as producing warmth and shelter, by its numerous chaly leaves, which are non-conductors.

1519. Trees are various; the most general are the ligular threads of bass matts; for espaliers some use withs, or tared cords or threads: on the continent, rushes (*Juncus effusus*) cut green and dried in the sun are used; and often wheat-straw. When mat, bark, rush, willow or other spray or shoots, or straw are used, they should be previously soaked a short time in water.

1520. Covering materials are straw, reeds, haulm of any sort, spray, &c. They may either be used loose, which when the weather is dry and calm, is the most effectual way of excluding cold; or drawn, that is, with the stalks or spray arranged in parallel lines in the manner of thatch, by which means the rain runs off, and then they exclude cold both in dry and wet weather. Sometimes straw and reeds are so prepared in frames, or rails suited to the size of beds in the manner of the reed, or spray, or wattled hurdle. (1499.) Sometimes they are covered with mats; but as the latter readily admit rain, this mode is much inferior to that of arranging the straw or reeds in the manner of thatch.

1521. Boards and planks are used in gardening, for wheeling up declivities, over steps and hollows, across borders, walks, &c. The notched or bridge-plank is used to protect edgings, serving as a bridge across them. Tresses are used for raising planks in extensive operations on the soil, in forming pieces of water, new gardens, or garden-scenery.

1522. Various prepared articles might be mentioned as of frequent or occasional use. Scoria from a forge is used for forming a platform impervious to worms, on which to place pots of plants. Soaper's ashes or waste is used for the same purpose. The use of gravel and sand is very general; fine sand, uncontaminated with ferruginous matter, is particularly useful in propagating heaths and other delicate plants by cuttings. Oystershells are used as crocs or sherd for covering the bottom holes of pots. Quick-lime in powder or infusions to destroy vermin, especially worms. Tobacco and other prepared matters are also used for the same purpose. Moss is used in packing and for other objects. Tanner's bark for its heat and fermentation.

**Chap. II.**

*Structures used in Gardening.*

1523. By garden-structures we mean to designate a class of buildings which differ from all other architectural productions, in being applied to the culture, or used exclusively as the habitations of plants. As edifices, the principles of their construction belong to architecture; but as habitations for plants, their form, dimensions, exposition, and, in many respects the materials of which they are composed, are, or ought to be, guided by the principles of culture, and therefore under the control of the gardener. They may be arranged into the moveable, as the hot-bed frame; fixed, as the wall, trellis, &c.; and permanent, as the hot-house.

**Sect. I. Temporary or Moveable Structures.**

1524. Of these, some are for protecting plants in fixed places, as against walls or trellises, and exemplified in the different methods of covering by frames of canvass, netting, or glass; others constitute habitations for plants, as the hot-bed frame, pit, &c.

**Subsect. 1. Structures Portable, or entirely Moveable.**

1525. Portable structures are the flower-stage, canvass or gauze frame or case, glass frame or case, glass tent, and glazed frame.

1526. Of the flower-stage there are two principal species; the stage for florists' flowers and the stage for decoration.

1527. The stage for florists' flowers, when portable, is commonly a series of narrow shelves rising in gradation one above the other, and supported by a frame and posts, so as to be 3 or 3 1/2 feet from the ground at the lowest shelf. These shelves are enclosed, generally,
on three sides by boards or canvass, and on the fourth side by glass doors. This stage, when in use, is placed so as the glazed side may front the morning sun, or the north, so as the colors of auriculas, carnations, &c. may not be impaired by him. (See Floriculture, Part III. Book II. Ch. VIII.)

1528. The decorative stage consists of shelves rising in gradation, in various forms, according to taste, and particular situation. Those to be viewed on all sides are commonly conical (fig. 222.) or pyramidal; those to be seen only on one side triangular. They are constructed either of boards or iron work, and placed in parterres, open courts, and large chambers.

1529. The opaque covering-frames are borders of board, strengthened by cross or diagonal slips of wood or rods of iron, and covered with canvass, gauze, woollen, or common netting, or soiled paper. They are used for protecting plants from cold, or for sheltering from wind, or shading, either singly, supported by props, or connected so as to form roofs, cases, or enclosures.

1530. The transparent covering, or glazed frame or sash, consists of a boundary frame composed of two side pieces called styles, and two end pieces called the top and bottom rails, with the interspace divided by rabbeted bars to contain the glass. It is used as the opaque covering frames, and has the advantage of them in admitting abundance of light. In general the rabbeted bars are inserted in one plane, as in common hot-bed sashes; but in some cases the surface is in angular ridges, or ridge and furrow-work (fig. 223.), cuneiform (fig. 224.), or trigonal (fig. 225.), in order, in each of these cases, to admit more of the rays of the sun in the morning and afternoon, and to moderate it in the middle hours of the day. Such frames are used for placing over beds of hot dung, for growing cucumbers, forcing roots or flowers, and for a great variety of purposes. The materials of sashes is commonly timber, but iron, cast and wrought, and copper, are also used.

1531. The common glass case is a glazed wooden frame or frames, so contrived as to fit together, and cover either single trees, espaliers, or shrubs too large for the hand-glass. The flavor of plums and cherries on espaliers in bad seasons is much improved by the use of this structure. In France it is chiefly used for peaches. For orange-trees, it consists of a number of frames, chiefly parallelograms, but partly right-angled triangles (fig. 226.), easily put together and taken asunder, to be used in the summer months in growing melons, or covering walls or espalier rails; and in winter in protecting orange-trees in situations where they are planted in rows against walls, or in groves in the open air.

1532. The hot-bed frame is of three species, the common, fixed-bottomed, and moveable-bottomed.

1533. The common hot-bed frame is a rectangular box of wood, bottomless and highest at the side to be placed to the north, subdivided by cross bars dove-tailed into the outer frame, and each subdivision covered by a glazed sash. Knight, instead of having the north side of the frame highest, has all the four sides of equal height, but forms the base meat of the dung-bed, and builds the dung-bed itself of that slope which he thinks most suitable for the sashes of hot-beds.

1534. The fixed-bottomed frame is the common hot-bed frame, with a boarded bottom for the retention of earth. In the boards are holes for the emission of water.

1535. The adjusting-bottomed frame has a box for the earth, of the size of the inside dimensions of the frame, and the frame being deep or placed on walls, like those of a pit, the bottom and its earth and plants, or its pots and plants, may be raised or lowered by a
power composed of a pinion and screw, or any other equally convenient power. The bottom is composed of perforated boards, and has boarded sides to keep in the earth. The object is to prevent plants from being burned when the dung is very hot, by raising them; to raise them close to the glass when young, and to lower them in cold nights. The chief difficulty in managing it is, to keep the earth of uniform moisture. Lawrence, in the last edition of his Kalendar (1715), suggests the idea of putting a bottom of wire to the frames of hot-beds, and of covering it with flat tiles, and over these the earth, &c. so as to admit of the whole being lifted, and the dung below stirred or renewed at pleasure. He says he has not seen it done, but merely suggests it as a hint to the ingenious. A century afterwards, J. Weeks, of the Horticultural Manufactory, King’s Road, London, invented his patent forcing-frame, which is that just described.

1536. Separating frames. The component parts of any of the above frames, instead of being mortised into one another, are fastened by keyed iron bolts, which easily admit of their being taken asunder and put under cover, when not wanted for use; these frames may, consequently, be preserved longer from decay, and are also more portable than the common sort.

1537. Mallet’s frame (fig. 227.) is the invention of a French horticulturist of that name, and the advantages it possesses are, 1. The admission of more light and solar heat from the elevated angle of the curvilinear roof; and, 2. The direct admission of the sun’s rays when air is given. Professor Thouin (Cours d’Agriculture, &c. art. Chassia) says that they have not been much used, owing to the cost of their first construction.

1538. The essential portable structures are the common hot-bed frame with flat sashes; and next in order, the canvas curtain or netting screen.

Subsect. 2. Structures partly Moveable.

1539. Plant-structures partly moveable are pits and adapted frames: the characteristic of the pit is, that it is surrounded by a wall of earth or masonry, enclosing a pit or bed for containing dung or bark. The characteristic of the adapted frame is, as the name imports, a hot-bed frame adapted to some structure of timber, masonry, or iron.

1540. Of the pit. The species are the earth, walled, fluid, vaulted, and pillar-pit.

1541. The earth or primitive pit is in part sunk in the earth, and in part raised above it by walls of loam or turf. On these walls, glass frames are sometimes placed, and at other times only mats or canvas frames. Such pits are used by nurserymen and market-gardeners, and answer perfectly for the preservation of half-hardy plants.

1542. The walled pit is also partly sunk in the ground, and in part raised above it; but instead of earth or turf walls, they are formed of brick or stone, finished with a wooden coping the width of the wall, in which cross rafters are mortised to support the sashes. For ordinary purposes, such as growing melons or young pines, or half-hardy plants, such pits need not be above five feet deep, and if only one sash between each rafter is to be used, they should not be above six or eight feet wide. Where double sashes, one lapping over the other are to be used, the width of the pit may be from eight to twelve feet. Artificial heat is supplied to such pits entirely from the bed of tan or leaves.

1543. The fluid pit (fig. 228.) is the same as the last described, with the addition of a flue, which either makes the circuit of the pit, or runs along and returns by its back wall. This is the most generally useful description of this class of buildings, as, whenever the heat of the bark or other fermentable matter subsides, or whenever the air in the pit is too moist, and in danger of generating damp, a fire can be lighted which will remove both evils.

1544. Scott’s fluid pit and Knight’s pit are both excellent varieties of this species, and will be described in treating of the pine and melon, for which they are particularly adapted.

1545. Buck’s fluid pit (fig. 229.), by the interior position of the flues, saves something in the length of the sashes, at the expense, however, of a greater first cost for the flues, and the obvious loss of a portion of the fire-heat ever afterwards. It is fully described in Hort. Trans. iv. 535.

1546. The vaulted pit, in its simplest form, is the walled pit, with an arch thrown from the front to the back wall. Under the arch the fire is made, or steam admitted: or in some
cases fermenting litter thrown in. A great improvement on this species of pit has been made by J. West, of Castle Ashby, Northamptonshire. The principle of the improvement is the facilitating the passage of the heat from the vault to the bed of earth over it by substituting a thin floor of boards or slates, or wattled hurdle, for brick-work; the walls are also flued, and the heat supplied is that of fermenting dung, litter, weeds, &c. On the whole it seems an excellent improvement. Nine years' experience enable its inventor to recommend it for neatness of appearance, the power of regulating the heat to the greatest nicety, and for forcing asparagus, strawberries, and the most delicate kind of cucumbers. By raising the walls of the pit higher above the earth, it is evident it would answer equally well for growing pines, or forcing shrubs, or any other purpose to which pits are applied.

1547. *In West's pit* the dung is placed in a chamber (c) three feet and a half deep, being about eighteen inches below the surface-line; the walls (g) which surround it are nine-inch brick-work; both on the front and at the back of the chamber are two openings (a), about two feet six inches square each, with moveable doors through which the dung is introduced; the doors fit at bottom into grooves (b), and are fastened by a wooden pin and staple at top. In front of the doors, is a small area (o) sunk in the ground, surrounded by a curb of wood, by which the introduction or removal of the dung is facilitated. Along the centre of the chamber is a bar (d), which serves as a guide for packing the dung; and across the top, at intervals of twelve inches, are placed, on their edges, cast-iron bars (h), two inches wide, and three quarters of an inch thick, to support a layer of small wood, bushes, and leaves (i), over which is laid the soil for the plants (k). Just below the level of the bars all round the dung-chamber, are holes (j), passing in a sloping direction through part of the wall into a cavity (g) in the upper part of the wall at the back front and both ends of the pit. In the exterior part of the back wall are holes with plugs (l), to let out the steam and heat at discretion.

![Diagram of West's pit (229)](image)

At the commencement of forcing, half the chamber is filled longitudinally with dung, and if the doors are kept shut, this will afford sufficient heat from twelve to eighteen days. As the heat declines the other half of the chamber is filled, and the temperature is kept up by additions to the top of the dung, on either or both sides, as it settles. When the united heat of the two sides ceases to be sufficient, the side first filled must be cleared out, and mixed with fresh dung and replaced, and so on, adding and turning as circumstances require. *(Hort. Trans. iv. 220.)*

1548. *As an improvement on the construction*
of this pit, we would suggest the perforation of the whole of the side walls (fig. 231. a) in order to admit the steam more readily than it can find admittance by a single range of openings adopted by West. Where pits on West's plan are already built, a substitute for this preparation in the side walls may be found in the application of a wattled hurdle against them (fig. 231. b), as has been adopted in the Comte de Vande's garden at Bayswater. On wet soils a hollow bottom is an obvious improvement.

1549. The pillar-pit, or Alderstone pit (fig. 232.), is constructed with cast-iron pillars of three feet in height (a, a), which being joined by plates of that metal, form a support to the wall on which the sashes rest. Above ground, this wall (b, b, b, b), of four or nine inches in thickness, is built on the iron plates, and carried the usual height of a cucumber-frame. On this, a coping, or plate, either of wood or iron, is placed, to which is fixed cross rafters either of wood or iron (c, c, c, c), to hold the sashes (d, d). Around the pit is a trench (e, e) of the same depth as the cast-iron pillars, and its exterior sides supported by a brick wall. The centre of the bed, under the sashes, is filled with dung or bark in the usual manner, and the surrounding trench is destined for linings, which being protected by the wall, and covered by boards (f, f, f, f), supported on cross pieces of iron, retain their heat longer, and are less influenced by changes in the atmosphere. The chief advantage alleged in favor of this frame, is the greater durability of the brick walls, than of frames of wood, and its more elegant appearance in a garden.

1550. Of adopted frames there are M'Phail's, or the frame with dung-flues, the pit with rising frame, and the frame with props.

1551. M'Phail's frame (fig. 233.) consists of two parts, the frame (a, a) and lights (b), which are of wood, and not different from those used for growing cucumbers, and the basement (c, d) on which the frame is placed, which is flues of brick-work, with the outer wall uniformly perforated. Against these perforated flues, linings of dung are formed, the steam of which enters the flue and heats the earth (e, e, e) in the centre of each light. The chief objections to this plan are the first-cost, and the greater consumption of dung, which some allege is required to keep up the proper heat. Its advantages are, that hot dung may be used without any preparation, by which much heat is gained; and in the winter months, when a powerful artificial heat is required, and (in the case of common hot-beds) is apt to burn the plants, they are here in the coldest part of the soil, and cannot possibly be injured by any degree of heat which can be communicated by dung.

1552. The pit with rising frame (fig. 234.) contains a basement-wall of brick-work of the height of the dung or bark (a, a), and in this is a perpendicular vacuity (b, b) in which a common frame (c, c) is placed, and by a spindle, pinion, &c. (d) may be raised or lowered at pleasure. Its object is the same as that of Weeks's frame already described, and which it attains with less risk to the plants, but at a great comparative expense. This variety of pit is the invention of John Nairn, (Hort. Trans. vol. iii. ) who has had it executed, and heated by surrounding tubes (e, e, e), filled with steam.
1553. The frame on props, in construction, resembles the Alderstone pit, excepting that the superstructure is a frame instead of masonry. Such frames are much used about London to grow pines, the back being enclosed by walled hurdles, supported by the props as stakes, and round the hurdles linings of dung are applied.

1554. There are a great many varieties of this species of frame: that adopted at Edmonton for the culture of pines will be noticed in treating of that fruit.

Sect. II. Fixed Structures.

1555. Fixed structures consist chiefly of erections for the purpose of improving the climate of plants by shelter, by supplying heat, and by exposing them to the influence of the sun. The genera are walls and espalier rails, of each of which the species are numerous.

1556. Garden-walls are formed either of brick, wood, stone, or earth, or brick and stone together; and they are either solid, flued, or cellular, upright or sloping, straight or angular.

1557. Brick, stone, or mud walls consist of three parts, the foundation, the body of the wall, and the coping. The foundation should be somewhat broader than the body of the wall, and of depth proportionate to the quality of the sub-soil, or intended plan of culture. In some cases where it is intended that the roots should have free access to both sides of the wall, it should be placed on arches (fig. 235.), or piers, with plank-stones, the soffit of the stone or under crown of the arch being within 6 inches, or 1 foot of the surface, and the openings, smaller or larger, according to the power of the materials to resist the pressure of the wall. The arch should be a segment of a circle, or an ellipse, and the piers (a, a, a) proportioned to the qualities of the foundation and the superstructure. Where the body of the wall commences, there will be a set-off or rebate of one or two inches on each side, which should be commenced below the ground’s surface, both for the sake of appearance, and to prevent the alternate action of the air and rain from rotting the mortar in the rebate. The body is generally carried up of the same width to the coping; but where the walls are high, say 18 feet, it may taper equally on both sides to 14 inches; in doing which, great care must be taken by the bricklayer to make good joints. To facilitate this, some architects have bricks formed of a smaller size for the upper part of the wall. It is not settled among gardeners whether the coping should project at all; or if it projects, how much, and what proportion on each side. Nicol is of opinion it need not project at all, and that there is no occasion, as is generally done, to bevel the coping stones to the north, or less useful side of the wall, to throw off the rain in that direction. Walls without copings have two advantages in their favor; the first is, that no insects are harbored in the angle, under the coping, as is generally the case; and the second, that trees are more readily trained over from one face of the wall to the other, a practice which has been found to induce a fruitful state in trees, which had never produced fruit before. There is also some saving in extent.
of coping. On the other hand, copings which have a considerable projection are known to protect wall-trees from spring frosts. We prefer for this purpose moveable copings. (1493.)

1558. The brick and stone wall is a stone wall faced with four inches of brick-work, or what is called brick and bed, on the side most exposed to the sun, as on the south sides of east and west walls, and on the insides for the sake of appearance of the two end, or north and south walls of enclosed gardens. Where free-working stone abounds on the spot, such walls are erected at much less expense than walls entirely of brick. Whether they are as dry, durable, and warm, depends on the sort of stone; some schistous and other argillaceous stones are apt to be damp, but compact limestones may be accounted as good as brick, and if they are of a dark grey or blue color, better on account of their absorption and refraction of heat.

1559. The solid brick wall is the simplest of all garden-walls, and where the height does not exceed 6 feet, 9 inches in thickness will suffice; when above that to 13 feet, 14 inches, and when from 13 to 20 feet, 18 inches in width are requisite. In most cases, such walls may be contracted in width as they are carried up, so that a 20 feet wall may begin with 18, and terminate in 9 inches in breadth. The contraction must be gradual from bottom to top; or if accomplished by rebates, they must be bevelled, by means of a course of sloping-edged or flanked bricks at each set off; and these must be made exactly alike on both sides of the wall, in order to preserve its centre of gravity exactly in the centre of the foundation.

1560. The flued wall, or hot-wall, (figs. 236, & 237.) is generally built entirely of brick, though where stone is abundant and more economical, the back or north side may be of that material. A flued wall may be termed a hollow wall, in which the vacuity is thrown into compartments (a, a, a, a), to facilitate the circulation of smoke and heat, from the base or surface of the ground to within one or two feet of the coping. They are generally arranged with hooks inserted under the coping, to admit of fastening some description of protecting covers (1495.), and sometimes for temporary glass frames. A length of 40 feet, and from 10 to 15 feet high, may be heated by one fire, the furnace of which (b), being placed 1 or 2 feet below the surface of the ground, the first course or flue (c) will commence 1 foot above it, and be 2 feet 6, or 3 feet high, and the 2d, 3d, and 4th courses (d, e, f), narrower as they ascend. The thickness of that side of the flue, next the south or preferable side, should for the first course be 4 inches, or brick and bed; and for the other courses it were desirable to have bricks cast in a smaller mould; say for the second course 3, for the third 2 1/2, and for the fourth, 2 1/2 inches in breadth. This will give an opportunity of bevelling the wall, and the bricks being all of the same thickness, though of different widths, the external appearance will be very where the same.

Sometimes a vacuity is formed between the flue and the south or valuable side of the wall (Hort. Trans. iv. 139.); but this, we think, may be considered an extravagant refinement. It cannot be carried into execution without employing a great quantity of materials and much labor. A wooden or wire trellis is also occasionally placed before flued walls; but both modes suppose a degree of forcing which does not appear ad-
visable unless the wall is kept constantly covered with glass, in which case, without
this precaution, constant fires might injure, by occasioning the partial growth of the
trees, or even burning those parts of them immediately opposite the furnace. To
prevent accidents of this kind, the furnace must always be placed at some distance,
say from eighteen inches to three feet from the back of the wall.

1561. The cellular wall (fig. 238.) is a recent invention (Hart. Trans. vol. iv.), the
essential part of the construction of which is, that the wall is built hollow, or at least
with communicating vacuities, equally distributed from the surface of the ground to the
coping. If the height does not exceed 10 or 12 feet, these walls may be formed
of bricks set on edge, each course or layer consisting of an alternate series of two bricks
set edgeway, and one set across, forming a thickness of nine inches, and a series of cells,
nine inches in the length of the wall, by three inches broad. The second course being
laid in the same way, but the bricks alternating or breaking joint with the first. The
advantages of this wall are obviously considerable in the saving of material, and in the
simple and efficacious mode of heating; but the bricks and mortar must be of the best
quality. This wall has been tried in several places near Chichester; and at Twickenham,
by F. G. Charmichael, and found to succeed perfectly as a hot-wall, and at 10 feet high
to be sufficiently strong as a common garden-wall, with a saving of one brick in three.
As a whole, indeed, it is stronger than a solid nine-inch wall, on the same principle that a
hollow tube is less flexible than a solid one. It is evident, that the same general plan
might be adopted in forming cellular walls of greater height, by increasing their width.
A very high wall might have two systems of cells divided vertically, one or both of
which might be heated at pleasure. The same idea may be advantageously applied to
flues, for heating hot-houses by steam, and for other purposes. Piers may be formed
either on both sides of the wall (c), or on one side by bricks on edge (b), so as to bond
in with the rest of the work.

1562. Hollow walls may also be formed by using English instead of Flemish bond:
that is, laying one course of bricks along each face of the wall on edge, and then bonding
them by a course laid across and flat. Such a mode has been practised and described by
Dearne, an architect in Kent.

1563. Where wall-fruit is an object of consideration, the whole of the walls should be flued
or cellular, in order that in any wet or cold autumn, the fruit and wood may be ripened
by the application of gentle fires, night and day, in the month of September. It is an
error to light the fires of hot-walls only in the evenings, the effect of heat in the process
of maturition being much greater when accompanied by light. In all hot-walls one
precaution must not be neglected, the building in, on the inferior or outer side, small
cast-iron doors, or framed stones, which may be opened at pleasure, in order to withdraw
the soil. They must be made perfectly airtight, which is readily accomplished by
having double cast-iron doors, in what is called Count Rumford's manner.

1564. The mud or earth-wall (fig. 239.) is formed of clay, or better of brick earth in a
state between moist and dry, compactly rammed and pressed together between two
moveable boarded sides (a, a), retained in their position by a frame of timber (b, b),
which form, between them the section of the wall (c, c); these boarded sides are placed,
inclining to each other, so as to form the wall tapering as it ascends; one layer of
the length of twelve or twenty feet being completed, another layer is formed on that,
Insects. Peaches are grown on them in France and Germany, but in this country, where the weather is more, variable, and the atmosphere more generally charged with vapor, particular attention requires to be paid to the coping. This attended to, these en pisé, or mud-walls, may be useful as shelters to cottagers' gardens, but rarely of much service as sources of wall-fruit. For a more particular account of their construction, see Com- munications to the Board of Agriculture, vol. ii.; or Nicholson's Arch. Dict. art. Wall.

1565. Boarded or wooden walls (fig. 240.a) are variously constructed. One general rule is, that the boards of which they are composed, should either be imbricated or close-jointed, in order to prevent a current of air from passing through the seams; and in either case well nailed to the battens behind, in order to prevent warping from the sun. When well tarred and afterwards pitched, such walls may last many years. They must be set on stone posts, or the main parts or supports formed of cast-iron. Nicol informs us (Kalender, p. 149.) that he has "constructed many hundred lineal feet of wooden walls, which recline considerably towards the north (fig. 240. b), presenting a surface at a better angle with the sun than if they were upright. They are placed on sloping ground, and range in five ranges or lines, due east and west, at the distance of seven yards from each other, the southmost being five feet high, and the northmost seven, composed of imbricated boards, pitched over to give them durability; the supports are set on (not in) blocks of stone, which are sunk in the earth, and firmly laid on solid foundations, three feet under the ground level."

1566. Inclined fruit-walls seem to have been first suggested about the beginning of the eighteenth century, by N. F. De Douillier, F. R. S. an able mathematician, author of a work entitled Fruit-walls improved by inclining them to the Horizon, &c. Some walls were formed at Belvoir Castle on this plan, which Switzer informs us he went to see, but found them damp, and the trees liable to be injured by perpendicular frosts. De Douillier's work, as being the production of a speculative theorist (he was tutor to the Marquis of Tavistock), appears to have been rejected by Miller, Switzer, Lawrence, and the designers of gardens of that day, but it is replete with ingenuity and mathematical demonstration, and well illustrates the importance of sloping walls where they are to be protected by glass or gauze. For exposed walls, it does not appear that this form will ever be adopted, chiefly on account of the difficulty of building them, the inutility of the northern or inferior side, and because, if formed in the most economical manner, they would not serve as fences. In particular situations, as in the case of terrace slopes, they certainly merit trial; and if covered in severe weather, there can be no doubt that their surface, by being more perpendicular to the sun's rays in summer, would receive a greater accession of light and heat at that season. In a communication to the Horticultural Society (vol. iv. p. 140.), by Stoffels, gardener at Mechlin, he states, "that he had an opportunity of comparing the effect of a sloping and perpendicular wall in the same garden, for the growth of peach-trees, and that the result was greatly in favor of the former." It appears to us, that for this and other fruit-trees that do not grow very rigid at the root or main stem, a boarded wall which might be inclined at pleasure, to an angle of 45° to both sides of the perpendicular, might be advantageously adopted. In the day-
time, or at least when the sun shone in the beginning of summer, it might be inclined to the north, (the trees being planted on the south side,) to give the trees the advantage of the sun; and during severe weather in autumn, or at any time when it was either desired to protect or retard the trees, it could be inclined to the south to protect them from dews and shade them from the sun's rays.

1567. The wavy or serpentine wall (fig. 241.) has two avowed objects; first, the saving of bricks, as a wall in which the centres of the segments composing the line are fifteen feet apart, may be safely carried fifteen feet high, and only nine inches in thickness from the foundations; and a four-inch wall may be built seven feet high on the same plan. The next proposed advantage is, shelter from all winds in the direction of the wall; but this advantage seems generally denied by practical men. Miller says, he saw them tried at Le Cour's in Holland, and that the trees which grew on them were in no respect superior to those on straight walls. They have been tried at different places in the northern and southern provinces of Britain, but are generally disapproved of as creating eddies.

1568. The angular wall (fig. 242.) is recommended on the same general principles of shelter and economy as the above; it has been tried nearly as frequently, and as generally condemned on the same grounds.

1569. The zig-zag wall (fig. 243.) is an angular wall in which the angles are all right angles, and the length of their external sides one brick or nine inches. This wall is built on a solid foundation, one foot six inches high, and fourteen inches wide. It is then commenced in zig-zag, and may be carried up to the height of fifteen or sixteen feet of one brick in thickness, and additional height may be given by adding three or four feet of brick on edge. The limits to the height of this wall is exactly that of a solid wall of fourteen inches thick; that being the width of the space traversed by the angles or zig-zag. That as a whole it is sufficiently strong for a fence against cattle, may be proved by applying to it the first problem in dynamics; the two diagonal lines formed by the zig-zag producing an equal resistance to one line directly across a fourteen-inch wall. In training on these walls, wires are stretched horizontally from angle to angle, and either four and a half, or nine inches apart, or upright rods of wood (a, a) may be employed; they are, however, better adapted for fences, or walls of botanic, flower, or nursery gardens, than for fruit-walls.

1570. The square fret wall (fig. 244.) is a four-inch wall like the former, and the ground-plan is formed by joining a series of half-squares, the sides of which are each of the proper length for training one tree during two or three years.

1571. The nurseryman's, or self-supported four-inch wall (fig. 245.), is formed in lengths of from five to eight feet, and of one brick in breadth, in alternate planes, so that the points of junction form in effect piers nine by four and a half inches. This wall is the invention of Lee, of the Hammersmith Nursery, and is well calculated for training peaches.
and other fruit-trees for public sale. It seems to be the most economical wall that can be devised, as the parts forming piers are as useful as any other parts of the wall, which is not the case with piered walls of the common sort.

1572. The piered wall (fig. 246.) may be of any thickness with piers generally of double that thickness, placed at regular distances, and seldom exceeding the wall in height, unless for ornament. These piers are generally made square in the plan; but they have been found to be less obstructive to the training of trees, when rounded at the angles (a); or angular (b), and either hollow, or effected by deviation (c). The same remark will apply to piers formed partly to support the wall, but principally as in the gardens laid out by London and Wise, Bridgeman, &c. for sheltering the fruit-trees. Where training is not a leading object, a thin deep projection (d) is much stronger as a whole, than the clumsy square piers generally formed by routine practitioners.

1573. Sheltering piers were formerly, in some cases, made of such a width and depth as to contain a niche for training a vine, and, in that case, they were frequently raised above the coping of the wall. Examples of such piers exist in the walls of the kitchen-garden at Claremont, built from the designs of Brown, and at Hatton in Scotland, built after a design by London and Wise.

1574. Arched, niched, or recessed walls (fig. 247.) were contrived for the same purpose by Switzer, and, at least, had a massive imposing effect to the eye. Such walls were generally heated by flues, and formed in fact the intermediate link in the progress of improvement between hot-walls and forcing-houses.

1575. Trellised walls are sometimes formed when the material of the wall is soft, as in mud walls; rough, as in rubble-stone walls, or when it is desired not to injure the face of neatly finished brick-work. Wooden trellises have been adopted in several places, especially when the walls are flued. Wire has also been used; and the following mode has been adopted by C. Holford, an ingenious horticultural amateur at Hampstead: “I affix copper wires from the top to the bottom of the wall, in a perpendicular direction, secured at each end by a small iron hook, two iron stair-staples are also driven in over the wires, at equal distances, to keep them nearly close to the wall. The wires may be placed at six to eight inches’ distance from each other. The branches and shoots are fastened by means of thin twine, which is first tied to the wire with a single knot, and then round the shoot more or less tight, according as it may be required to check or encourage the circulation of the sap; with a very little practice this may be done with great expedition. The wire which I have used is of the substance measuring about twenty yards to the pound weight, and as it does not oxidate by exposure to the atmosphere, will not require painting, and will last for years. The expense is about one penny per yard. I have not found the peaches and nectarines to be at all retarded by this mode of training.” (Hort. Trans. v. 569.)

1576. Espalier rails are substitutes for walls, and which they so far resemble, that trees
are regularly spread and trained along them, are fully exposed to the light, and having their branches fixed are less liable to be injured by high winds. They are formed of wood, cast-iron, or wire and wood.

1577. The wooden espalier, of the simplest kind, is merely a straight row of stakes driven in the ground at six or eight inches asunder, and four or five feet high, and joined and kept in a line at top by a rail of wood, or iron hoop, through which one nail is driven into the heart of each stake. If the lower ends of the stakes are charred, and the sort of wood be larch, oak, ash, or birch, with the bark adhering, they will last for many years; but stakes of young Scotch pines or poplars lose their barks and soon decay. Young larch-trees are much the most durable.

1578. The framed wooden espalier rail is composed of frames fitted with vertical bars at six or eight inches asunder, which are nailed on in preference to mortising, in order to preserve entire the strength of the upper and lower rails. The end styles or uprights of the frame are set on stone piers, and attached and kept upright by irons inserted into the stone. This is the most frequent mode of construction, but sometimes the frame is fitted in with lattice-work, or wire, or stout laths; and instead of stones, oak posts, or posts of fir charred, are driven into the ground, to which to attach the styles of the frames.

1579. The cast-iron espalier rail, (fig. 248) resembles a common street railing, but it is made lighter. The columns or styles may either be fixed in oak or stone (a, a); or, when this mode is not adopted, to form their base in the shape of a reversed -., setting them on a foundation of four-inch brick-work. Such espalier rails have been tried in Scotland (Caled. Mem. i. 483,), and found to come somewhat cheaper than wooden ones; but their great advantage must be their durability, (especially when well painted, or oiled, whilst the iron is hot,) and the elegance of their appearance.

1580. The horizontal espalier rail (figs. 249, & 250) is a frame of wood or iron, of any form or magnitude, and either detached or united, fitted in with bars, and placed horizontally, at any convenient distance from the ground. For dwarf trees the common height is three feet, and for standards, six feet. In the latter case, the frames may be arched, and the trees trained so as to form a bower, covered way, &c. These have not been much used, nor, from the loss of ground, and the too violent constraint on the tree, is it likely they will ever become general.

1581. The oblique espalier rail is composed of frames of bars, wires, or lattice-work, placed obliquely. (Hort. Trans. App. to vol. ii.) Trees will no doubt thrive well, trained on such surfaces, but, unless they run north and south, one side will be of little use; and even running north and south, they can only enjoy half the day’s sun. The ground too under them, unless used as a walk, must be in a great degree lost, so that these rails are on the whole inferior to the common sort.

1582. Of fixed structures, the brick wall, both as a fence, and retainer of heat, may be reckoned essential to every kitchen-garden; and in many cases the mode of building them hollow may be advantageously adopted.
### Sect. III. Permanent Horticultural Structures.

1583. **Buildings with glass roofs**, or artificial habitations for plants, constitute by far the most important part of garden-structures, whether we regard the expense of their first erection, the skill required to manage them, or the interesting nature of their products.

1584. **Green-houses were known in this country in the seventeenth century.** They were then, and continued to be, in all probability, till the beginning of the 18th century, mere chambers distinguished by more glass windows in front than were usual in dwelling-rooms. Such was the green-house in the apothecaries' garden at Chelsea, mentioned by Ray, in 1684. (Letters, p. 174.) as being heated by hot embers put in a hole in the floor; a practice still extant in some parts of Normandy, and to which, as is well known, the curfew, or couvre-feu bell refers. The same general form of house with the addition of a furnace or oven is given by Evelyn in the different editions of his *Kalendarium*.

1585. **The first era of improvement** may be dated 1717, when Switzer published a plan for a forcing-house, suggested by the Duke of Rutland’s graperies at Belvoir Castle. Miller, Bradley, and others, now published designs, in which glass roofs were introduced; and between the middle and the end of the last century, Speechley and Abercrombie in England, and Kyle and Nicol in Scotland, made various improvements in forcing-houses, as to general form, internal arrangements, and mode of heating. The largest plant-stoves were the joint productions of the late W. Aiton, and Sir W. Chambers at Kew, and the largest pineries were erected at Wellbeck by Speechley.

1586. **A second era of improvement** may be dated from the time when Dr. Anderson published a treatise on his patent hot-house, and from the publication of Knight’s papers in the *Horticultural Society’s Transactions*, both of which happened about 1809. Not that the scheme of Dr. Anderson ever succeeded, or is at all likely to answer to the extent imagined by his inventor; but the philosophical discussion connected with its description and uses, excited the attention of some gardeners, as did the remarks of Knight on the proper slope of glass roofs (*Hort. Trans.* vol. i.); and both contributed, there can be no doubt, to produce the patent hot-houses of Stewart and Jorden, and other less known improvements. These, though they may now be considered as reduced au merite historique, yet were really beneficial in their day. Knight’s improvements chiefly respected the angle of the glass roof; a subject first taken up by Boerhaave about a century before, adopted by Linnaeus (*Amen. Acad. i.* 44.), and subsequently enlarged on by Faccio in 1699, Adanson (*Familles des Plantes*, tom. i.) in 1763, Miller in 1768, Speechley in 1789, John Williams of New York (*Tr. Ag. Soc. New York*, 2d edit.) in 1801, Knight in 1806, and by some intermediate authors whom it is needless to name.

1587. **The last and most important era** is marked by the fortunate discovery of Sir G. Mackenzie in 1815, “that the form of glass roofs best calculated for the admission of the sun’s rays is a hemispherical figure.” This may be considered as the ultimatum in regard to the principle and perfection of form; and has already given rise to many beautiful curvilinear structures, of which a series of plans are in course of publication by Messrs. W. and D. Bailey, of Holborn, London, who have erected curvilinear houses at the following places:

1588. Great emulation now exists in this department of horticulture, not only among country gentlemen, but also among commercial gardeners. One house for growing palms and seetamine, erected by Messrs. Loddiges, is 45 feet high and 60 feet wide, and another by the same nurserymen for green-house plants, is 23 feet wide, 18 feet high, and upwards of 100 feet long, without a single rafter or standard: and these spirited cultivators, and also Messrs. Gunter, Grange, Wilmot, Andrews, and others, have heated the whole of their extensive ranges of glass by steam.

1589. The application of steam to the heating of hot-houses appears first to have been attempted by Wakefield of Liverpool, in 1788, and afterwards effectually applied in the vault of a cucumber-house at Knowle in that neighbourhood, by Butler, gardener to the Earl of Derby, in 1792. It made little progress till about 1816, since which it has extended rapidly, and wherever an extensive range of hot-houses are to be heated, it will be found a saving of fuel and labor, attended with less risk of over heating or con-
tamination by bad air.

1590. The grand cause of the improvements which have been made in hot-houses, may be traced to their being no longer as formerly under the control of mansion architects. To civil architecture, as far as respects mechanical and chemical principles, or the laws of the strength and durability of materials, they are certainly subject in common with every description of edifice; but in respect to the principles of design or beauty, the founda-
tion of which we consider, in works of utility at least, to be "fitness for the end in view," they are no more subject to the rules of civil architecture, than is a ship or a fortress; for those forms and combinations of forms, and that composition of solids and openings which are very fitting and beautiful in a habitation for man or domestic animals, are by no means fitting, and consequently not beautiful in a habitation for plants. Such, however, is the force of habit and professional bias, that it is not easy to convince architects of this truth; for structures for plants are considered by them no further beautiful than as displaying not only something of architectural forms, but even of opaque materials. Fitness for the end in view, we repeat, is the basis of all beauty in works of use, and, therefore, the taste of architects so applied, may safely be pro-
nounced as radically wrong. — We shall consider the subject of hot-houses as to the principles of construction, external forms, and interior details.

Subject. 1. Of the Principles of Design in Hot-houses.

1591. To ascertain the principles of action, it is always necessary to begin by considering the end in view. The object or end of hot-houses is to form habitations for vegetable, and either for such exotic plants as will not grow in the open air of the country
1592. Such heat as is required in addition to that of the sun is most generally produced by the ignition of carbonaceous materials, which heat the air of the house, either directly when hot embers of wood are left in a furnace or stove, placed within the house, as in Sweden and Russia; mediately, as when smoke and heated air, from, or passing through ignited fuel, is made to circulate in flues; or indirectly, when ignited fuel is applied to boil water, and the hot vapor, or the water itself, is impelled through tubes of metal or other conductors, and either to heat the air of the house at once, as in most cases, or to heat masses of brick-work, sand, gravel, rubble, or earth, tan, or even water. (Hort. Trans. vol. iii.) which materials may afterwards give out the heat so acquired slowly to the atmosphere of the house. But heat is also occasionally supplied from fermenting vegetable substances, as dung, tan, leaves, weeds, &c. applied either beneath or around the whole or a part of the house, or placed in a body within it.

1593. In particular situations heat may be obtained from anomalous sources, as in Iceland, Tepplitz, and Matlock, from hot springs; and perhaps in some cases, especially in coal districts, from a basement composed of certain compounds of sulphur and iron, &c. Dr. Anderson (Treatise on the Patent Hot-house,) proposed to preserve the superfluous heat generated by the sun in clear days, and to retain it in reservoirs placed under, above, or at one side of the house, re-admitting it as wanted to keep up the temperature; but the plan, though ingenious and philosophical, required too much nicety of execution, and the clear days in this country are too few to admit of adopting it as a substitute for heating by ignition. Heat must not only be produced in hot-houses, but its waste avoided, by forming as large a portion of the cover as possible of materials through which it escapes with difficulty, as far as this is consistent with other objects. Hence, in certain classes of houses, the side to the north is formed of opaque and non-conducting materials.

1594. Light is admitted by constructing the roof, or cover, of transparent matter, as oiled paper, talc, or glass, (the last being found much the best material,) joined to as small a proportion of opaque substances, as timber or metal, as is found consistent with the strength requisite to bear the weight of the glass, resist the accidents of weather, &c. All plants require perpendicular light, but some, as many succulents and others, which throw out, or are allowed to radiate their branches on all sides, require the direct influence of light on all sides; others naturally, as creepers or climbers, or artificially, when rendered creepers or climbers, by the art of training on walls or trellises, require direct light on one side only; and hence it is, that for certain purposes of culture, hot-houses answer perfectly well when the transparent covering forms only a segment of their transverse section, provided that segment meets the sun's rays at a large angle the greater portion of the growing season. This, of course, is subject to limitations and variations according to circumstances, and has given rise to a great variety in the external forms of hot-houses, and the angles of their roofs. It decides, however, the necessity of placing all houses whose envelope is not entirely transparent, with their glazed side to the south.

1595. The introduction and management of light is the most important point to attend to in the construction of hot-houses. Every gardener knows, that plants will not only not thrive without abundance of light, but will not thrive unless they receive its direct influence by being placed near or at no great distance from the glass. The cause of this last fact has never been satisfactorily explained. (Soverby on Light and Colors, 1816.) It seems probable, that the glass acting in some degree like the triangular prism, partially decomposes or deranges the order of the rays. It is an important fact also, that light in nature is always accompanied by heat; and, therefore, it should not only be an object to admit the sun's direct rays in clear weather, when he is visible, but even when the rays are refracted and deranged by clouds and vapors, when he is invisible.

1596. The theory of the transmission of light through transparent bodies, is derived from a well known law in optics, that the influence of the sun's rays on any surface, both in respect to light and heat, is directly as the sine of the sun's altitude, or in other words, directly as his perpendicularity to that surface. If the surface is transparent, the number of rays which pass through the substance is governed by the same laws. Thus, if 1000 rays fall perpendicularly upon a surface of the best crown-glass, the whole will pass through, excepting about a fourtieth part, which the impurities of even the finest
principles of design in hot-houses.

1597. The benefit derived from the sun's influence on the roofs of hot-houses depends, as far as respects form of surface, entirely on this principle. Boerhaave applied it to houses for preserving plants through the winter, and of course required that the glass surface should be perpendicular to the sun's rays at the shortest day, when most heat and light were required. Miller (Dict. art. Stat.) applied it to plant-stoves, and prefers two angles in the roof; one, as the upright glass, to meet the winter's sun nearly at right angles, and the other, as the sloping glass, to meet him at an angle of 45° for summer use, and "the better to admit the sun's rays in spring and autumn." Williamson (Hort. Trans. vol. i. p. 161.) prefers this angle (45°) in all houses, as do most gardeners, probably from habit; but Knight prefers, in forcing-houses at least, such a slope of roof as shall be at right angles to the sun's rays, at whatever season it is intended to ripen the fruit. In one of the examples given (Hort. Trans. vol. i. p. 99.), his object was to produce a large and highly flavored crop, rather than a very early crop of grapes; and he accordingly fixed upon such a slope of roof as that the sun's rays might be perpendicular to it about the beginning of July, the period about which he wished the crop to ripen. The slope required to effect this purpose in latitude 52°, he found to form an angle of 34° with the plane of the horizon. In the application of the same principle to the peach-house (Hort. Trans. vol. i. p. 206.) in order to ripen the fruit about midsummer, the roof was made to form an angle with the horizon of 28°. Both these houses, Knight assures us, produced abundant crops perfectly ripened.

1598. As data to determine the angles of glass roofs, the following are laid down by Wilkinson. The angle contained between the back wall of the forcing-house, and the inclined plane of the glass roof, always equals the sun's altitude, when his rays fall perpendicularly on that plane, provided that the inclination of the plane to the horizon be at an angle not less than 28° 2', nor greater than 75°. Within the above limits, the sun's rays are perpendicular twice in the year, once in going to, and once in returning from, the tropic. Hence then, having determined in what season we wish to have the most powerful effects from the sun, we may construct our houses accordingly by the following rule. Make the angle contained between the back wall of the house and its roof, equal to the complement of latitude of the place, less or more the sun's declination for that day on which we wish his rays to fall perpendicularly. From the vernal to the autumnal equinox, the declination is to be added, and the contrary. Thus, to apply these principles to the slope of roof recommended by Knight, for ripening grapes in July; say at London we have

<table>

<th>51° 22'</th>
<th>17° 31'</th>
</tr>
</thead>
</table>

33° 48' or 34° nearly.

Wilkinson adds that "as we want the genial warmth of the sun most in spring, therefore, for general purposes, that construction would perhaps be best which gives us the greatest quantity of perpendicular rays then. If the inclination were 45°, the sun's rays would be perpendicular about April 6th and September 4th. And as the rays would vary very little from the perpendicular for several days before and after the 6th of April and September 4th, the loss of rays arising from reflexion, would, as appears from the annexed table, be nearly a minimum. Even at the winter solstice, the loss by the obliquity of the angle of incidence would be only two in 1000 more than when the rays fall perpendicularly, as appears by Bouguer's Table of Rays reflected from Glass.

Of 1000 incidental rays when the angle of incidence is

When, in addition to this, it is considered, that the slope of 45° is the least that will effectually drain the water from the intervals between the lapping over of the panes of glass, that angle appears to us, as Williamson suggests, decidedly the best slope for general purposes.

1599. Air is supplied by the portion of the atmosphere enclosed by the tegument. This air may be raised in temperature, charged with vapors, or renewed, at the will of the operator. It might also be put in motion by art, for the sake of obtaining strength of stem in ramose or tree-like plants; but the motion communicated to plants, by opening the cover, and exposing them to the direct influence of the air in fine weather, is deemed sufficient, either for this purpose, or giving flavor to fruits when advancing to maturity. A very fit machine for putting air in motion, or for extracting air, was invented by B. Deacon (Patent-office, 1812, and Remarks on Hot-houses, part 2.) It
is impelled by manual labor, or clock or jack machinery, and has been successfully used for ventilating public rooms and churches.

1600. **Soil**, it must be obvious, is perfectly within the control of art, which, in fact, can far surpass nature, when increased dimensions of the parts of plants and improved quality of fruit are objects.

1601. **Water** is equally at our command with soil: it may be made to pass through the house in a surface-rill; or under the soil in subterraneous channels; may be retained in a cistern or basin; or introduced in tubes, either to throw up innumerable jets from the floor, or pour them down from the roof to serve as rain. It may be supplied directly to the roots of plants, without wetting their leaves, in the manner of irrigation; be stagnated round them, as in natural marshes, or made to ascend as vapor from steam-pipes, by pouring it on flues or hot bodies, or even watering the floor of interior surface of the house. Having ascended and filled the air, it parts with its calorif, and is precipitated on the plants in the form of dew.

**Subsect. 2. Forms of Hot-house Roofs.**

1602. *The general form and appearance of the roofs of hot-houses,* was, till very lately, that of a glazed shed or lean-to; differing only in the display of lighter or heavier framework or sashes. But Sir George Mackenzie’s paper on this subject, and his plan and elevation of a semi-dome (*Hort. Trans.* vol. ii. p. 175.), have materially altered the opinion of scientific gardeners. Knight made the first observations on this figure. Sir George Mackenzie’s plan for forcing-houses, he observes, is extremely interesting; but contains "some defects which cannot be obviated without deviating from the spherical to the spheroidal form, which Sir George states to be objectionable, on account of the great nicety requisite in the workmanship. On making a few trials, to ascertain the varieties of forms which might be given to forcing-houses, by taking different segments of a sphere, I, however, soon became perfectly satisfied that forcing-houses, of excellent forms, for almost every purpose, and of any convenient extent, might be constructed without deviating from the spherical form; and I am now perfectly confident, that such houses will be erected and kept in repair at less expense, will possess the important advantage of admitting greatly more light, and will be found much more durable than such as are constructed according to any of the forms which have been hitherto recommended. By employing a small segment (fig. 251. b, c) of a large sphere (fig. 251. a, a), as low and as wide a forcing-house as can be wanted for any purpose, may be readily obtained. Instead of the half of a hemisphere of thirty feet diameter, let the half of one of fifty feet (a, a) be chosen, and from the base of this, cut off thirty-five degrees (b, b), and from the summit fifteen degrees (c, c); and the following proportions for a forcing-house (fig. 251. b, c) will be given. Its height (including eighteen inches of upright opaque front, opening as shutters,) will be twelve feet; its width in the centre fourteen feet, and its length very nearly forty feet; and there are very few purposes for which a house, constructed according to some of the intermediate forms, between that above mentioned and the acuminated semi-dome, will not be found extremely well adapted." A few observations on Sir G. Mackenzie’s plan, and the improvements on it, proposed by Knight, were made by Neill (*Edin. Encyc. art. Hort.*) and the next in order by us in Remarks on the Construction of Hot-houses, *Sc.* 1817. A year before (1816) we had invented a wrought-iron sash-bar, the section of which (fig. 252. a) is not more than half an inch wide, and a half bar (fig. 252. b) equally light (a specimen of both of which was presented to the Hort. Soc. in May 1816.); and in 1818 we completed a considerable erection of glass roofs at Bayswater (fig. 253.), on the curvilinear principle, the first, we believe, attempted in Britain. The object of such a junction of different curvatures in the Bayswater example is to show,
FORMS OF HOT-HOUSE ROOFS.

that, in regard to form, the strength and tenacity of the iron bar, and the proper choice of shape in the panes of glass, admits of every conceivable variety of glazed surface. In this we have completely succeeded, without in the least interfering with the objects of culture. To render all these improvements available by the public, as matters of trade, we transferred, in 1818, our right in the invention of the bar to efficient tradesmen (W. and D. Bailey, 272. Holborn, London), who have since, from our plans, constructed in a most excellent style of workmanship, the curvilinear houses in different parts of the country, of which we have already given a list and description. (1587.)

1603. Some forms of hot-houses on the curvilinear principle shall now be submitted, and afterwards some specimens of the forms in common use; for common forms, it is to be observed, are not recommended to be laid aside in cases where ordinary objects are to be attained in the easiest manner; and they are, besides the forms of roofs, the most convenient for pits, frames, and glass tents, as already exemplified in treating of these structures.

1604. The acuminated semi-globe. (fig. 254.) The most perfect form of a hot-house is indisputably that of a glazed semi-globe. Here plants, as far as respects light, would be nearly in the same situation as if in the open air; and art, as already observed, (1592.) can add heat, and all the other agents of vegetation, nearly to perfection. But in respect to excluding the rain, the semi-globe is too flat at top, and requires to be acuminated; and in regard to economy, the first cost and expense of maintaining an artificial heat against its constant abdution through a thin medium, exposed to the north winds, would, for most purposes, be a great objection.

1605. An acuminated semi-dome, or a vertical section of the last figure, placed against a wall built in a direction from east to west, removes a great part of the objection as to heat, and will still admit an adequate supply of light to plants kept constantly in the same position, or turned very frequently. This, therefore, may be reckoned the second best form for a plant-habitation for general purposes, and without reference to particular modes of culture.

1606. The semi-ellipse (fig. 255.) is a figure which, in the plan (a, a), displays half an
ellipses, or oval, and in the superstructure \((b, b)\) one-fourth part of the solid figure. Its advantage over a semi-dome is, that, whether the trees are to be trained on a trellis parallel to the glass, or against the back wall, a greater surface for training is obtained in proportion to the volume of cubic air to be heated. On the other hand, its glass surface is less perfect in respect to perpendicularity to the sun's rays; though in this respect the difference is not of great consequence. Houses of this sort, Adanson informs us, are of Dutch invention. As the sun retired from them in the afternoon, the eastern parts of the ellipse, as they fell successively into shade, were covered with reeds or mats; and, in like manner, in the morning the east end was uncovered first, and the west end only as the sun came round on it. (Familles des Plantes, vol. i. Pref.)

1607. The parallelogram with curved roof and ends (fig. 256.) is one of the most convenient forms of curvilinear roofs for the common purposes of culture, as it admits of more regular figures of beds, paths, trellises, &c. within, and of every variety of dimension. In regard to light, heat, and beauty, they do not differ materially from the semi-ellipse. Of this form, a considerable number of forcing-houses, and some green-houses, have been erected. Among the latter may be noticed one for Messrs. Loddiges, and another for the Horticultural Society. (See the Table, 1587.)

1608. The ridge and furrow roof may be effected either in curvilinear or right-lined hot-houses; and consists in placing the bars in the rebates of which the glass is put, in such a manner as that the section of the roof may always be a zig-zag line, in which the space traversed by each side or zig may either contain several bars (fig. 257.), or merely one pane of glass. (fig. 258.) In both modes it is generally desirable, that the ends of all the bars should terminate in one horizontal line on the top of the parapet; which need not, however, be the case in their termination against the back wall. Some apparent difficulty of glazing is thus occasioned in the lower part of the roof; but the difficulty is only apparent, for as smaller and only triangular pieces of glass can be used there, it becomes, in fact, more economical, by occasioning the use of pieces of glass which would otherwise be thrown away. The advantages of ridge and furrow roofing are chiefly obtainable in countries liable to heavy falls of snow or hail, and in houses which are parallelograms in plan. Almost any weight of snow may be carried by such roofs, especially when the bars are not far apart, as the pressure will evidently be almost entirely on the upper bars, and not on the glass. As to hail, as it will always meet the surface of the glass in a ridge and furrow roof at an angle of 45°, it can never do it much, if any, harm. Curvilinear houses with roofs of this description are therefore peculiarly suitable for the north of Europe, and especially for Russia; and in houses with triangular and straight-lined roofs, the sun (a, figs. 257. & 258.) will be perpendicular to half the roof (by being so to half each ridge) at that period which forms half
the time between his rising and mid-day, and perpendicular to the other half, at half the period of time between mid-day and sunset. Another advantage of ridge and furrow roofs is, that the laps between the panes, unless very broad or puttied, are always kept free from accumulations of dust. This takes place in consequence of their angle of inclination, which being about 45°, the gravity of the column of water between the laps is found to counterbalance the attraction of cohesion, and slides in the lap from the crown to the bottom of the furrow.

1609. The general form and appearance of a ridge and furrow house (fig. 259.) is not materially different from that of others. Where the curved end is adopted, it will not be necessary to deviate from the common mode of glazing in these parts of the roof, unless with a view to the roof, therefore, is ridged (fig. 260. a, a), the ends will present a smooth surface (fig. 260. b, b).

1610. The polyprosopic hot-house (fig. 261.) resembles a curvilinear house, but differs in having the surface thrown into a number of faces, the chief advantages of which are, 1. That by hinging all the different faces at their upper angles, and by having rods connecting the lower outside corners of the faces terminating in chains which go over pulleys in the top or above the back wall, the whole roof, including the ends, may be opened or raised sympathetically, like Venetian blinds (fig. 261. a.), either so as each sash or face may be placed in the plane of the angle of the sun’s rays at the time, or to the perpendicular, to admit a shower of rain.

In consequence of this arrangement, the plants in a polyprosopic house may, at any time, and in a few minutes, be placed in effect, or as far as respects light, air, wind, rain, dew, &c. in the open air; and being so placed, may, whenever desired, be as speedily restored again to their proper climate. The arrangement by which this is effected, and which is perfectly simple, is applicable to every form of hot-house, whether of glass on all sides, on two, or on three sides; or whether the roof is formed of curved or straight lines. We consider it, indeed, to be the ne plus ultra of improvement, as far as air and light are concerned. One objection to all curvilinear forms in this respect is, that the roof, unless a considerable expense be incurred, must be fixed, and air admitted by horizontal wooden or glazed shutters in the parapets, or between the props, and allowed to escape by skylights or shutters at the top of the back wall; but here the air is equally admitted in every part of the house, in the most natural manner, without the creation of currents or eddies, and without excluding any more sun than will be obstructed by the thickness or edge of the faces or sashes. In like manner, a great objection to straight-lined roofs with sliding sashes is, that air can only be partially admitted, and that while this is being done, one glazed frame being slid over the other in all those parts where there is a double portion of glass, a double portion of light must be excluded; and as opticians are aware, the light so transmitted will be doubly decomposed by passing through two surfaces of glass.

1611. This roof, with respect to the sun’s rays, may be considered as exactly equivalent to a curvilinear figure whose curve lines shall touch all the angles of the faces, so that the sun in general would be nearly perpendicular to some one face every hour in the day, and every day in the year. A specimen of glass roof, constructed on this principle, formed a part of the erection at Bayswater (1602.), already referred to, but which owing to local alterations it became necessary to remove in 1823.
1612. A range of hot-houses (fig. 262.) of any or of all the different varieties of curvilinear surfaces, every one will allow to have a better effect than the common glazed sheds or lean-to hot-houses of kitchen-gardens.

1613. Lean-to glass roofs are of various sorts. The simplest and most economical hot-house of this description may be compared to a large pit. The back and front walls and ends being of masonry, and a sloping side above of glass, and either fixed or moveable; if fixed, then air is admitted by openings in the front wall and top of the back wall; if moveable, the sashes slide, or are moved in grooves, the lower one being drawn up, and the upper sash let down. Such a house will succeed perfectly well for grapes and pines. The first improvement on this form consists in forming moving glass frames in front, instead of the opaque wall of masonry and shutters; a second consists in adding glass ends; a third, in forming the roof into two slopes; and a fourth, in bevelling the positions of the front sashes, and forming the whole roof into three different slopes, the lower for receiving the sun’s rays in winter; the second for spring and autumn; and the third, for midsummer.

1614. A variety of other forms will afterwards be given, both regular and anomalous, adapted to specific purposes of culture, particular situations, as conservatories or cabinet appendages to mansions, or for variety in flower-gardens.

Subsect. 3. Details of the Construction of Roofs, or the glazed Part of Hot-houses.

1615. The glazed tegument, or cover, may either be wholly fixed, wholly moveable, or partake of both modes. Each of these varieties may be considered in respect to component parts and materials.

1616. Fixed roofs are either formed of a series of bars of iron or wood, proceeding at once from the front parapet to the back wall; or from the base to the centre, or they may be composed of sashes placed beside each other, or between rafters, as in common lean-to houses. Roofs of this fixed kind have been approved of by Knight for vines; by Beattie, of Scone, for peaches; and by most cultivators for the culture of pines and palms; but, excepting for the two latter purposes, the general experience of gardeners is (in our opinion, very justly,) against them. It is to be observed, that in all cases of fixed roofs, shutters for ventilation are formed in the parapet, and in the upper part of the back wall immediately under the roof. Economy in first cost, and less breakage of glass afterwards, are the chief arguments in their favor; the latter advantage, however, is generally denied, it being improper glazing rather than the moving of the sashes, which occasions the breakage of glass.

1617. Moveable roofs are generally composed of sashes, six or eight feet long, and three or four feet wide, which slide over each other, and are moved by cords and pulleys, and sometimes balanced by weights, to facilitate their motion; but they are also occasionally formed of sashes which open outwards by means of iron levers at their lower extremities, and hinges at their upper angles (fig. 263.), in the manner of the polyprosopic house. (fig. 261.)

1618. Roofs partaking of both characters generally have a few sashes which let down or rise up in the roof or front glass; or in the case of domes or acuminated roofs, the top part rises in the manner of a sky-light.

1619. The material of fixed roofs is generally iron, as being least bulky in proportion to the strength required, most durable, and admitting, in the case of curvilinear roofs, a curvature to be formed at less expense than it could be of timber. In these roofs, in general, no other bars or opaque bearers are required than those for receiving the glass; and hence their simplicity and unity with regard to component parts, and the equal degree of transparency in every part of the surface.

1620. The materials of moveable roofs are most commonly timber; but frequently also timber and iron, or timber and copper joined together. Thus cast-iron and wrought-iron rafters are frequently used; and in these are placed sashes with styles and rails of timber, and bars of copper, and of cast or wrought iron. Two of the lightest-roofed shed-houses yet built with sliding sashes are, one by Timmins, of Birmingham, in 1811, at Loddiges’ nursery, in which the rafters are of wrought-iron, cased in copper, to which are screwed pulleys, on which the sashes, composed of copper bars and timber styles, slide without grooves; and the other is at the Union Nursery, King’s Road, erected by J. S. Jorden, in 1815, in which the upper part of the roof only moves; the rafters are trusses of wrought-iron, supporting bars of cast-iron; and the entire sash is formed of hollow sheet-
copper. The use of sheet-copper, however, may now be considered as exploded in hot-house building, wrought-iron being a much more economical, wholesome, durable, and equally elegant substitute for timber. In general, it may be observed, that where sashes and rafters are used in the formation of moveable roofs, a mixture of timber and metal is better than timber alone, the former in extremes of temperature being liable to expansion and contraction. Thus sashes with iron bars, and the outer frame or the styles and rails of timber, move readily in the grooves of cast-iron rafters, because when the metal expands with great heat, the timber in a slight degree contracts. The reverse is also the case, and cast-iron sashes slide readily in timber rafters. In both cases small rollers should be inserted, either into the sides of the sash or the fillet or groove of the rafters, or both. Cast-iron rafters need not, for general purposes, be more than half an inch thick, and six or eight inches deep; where the house is wide, they require to be supported by slender pillars. Wrought-iron rafters may be rolled out of broad bar-iron (fig. 264.), so as to present as light and elegant an appearance as our moulded wrought-iron sash-bar. (fig. 252.)

1621. Arrangements for covering the roofs of hot-houses by boards, canvas, or mats, to be lifted or rolled up or down, might be easily contrived and advantageously used; but excepting in pits and low hot-houses, they are not thought worth attending to, it being considered better to gain the admittance of all the light possible, than lose it for the sake of a little economy in fuel.

1622. The pillars or props which are placed on the parapet, to support the rafters, whether of timber or iron, are generally formed of the same thickness as the rafters, because similar sashes are placed between them.

1623. Interior uprights to support wide roofs are almost always of iron, either wrought-metal or small cast-iron columns, sometimes forming intersecting arches, or trellaged capitals, or connecting props for training creepers.

1624. The wall-plate, or coping of the parapet, is sometimes a plate of timber, sometimes of stone, and occasionally of cast-iron. Wherever upright glass is not employed, it must of necessity form also the guttering for the water of the roof, and at the same time for the water which condenses on the glazed inside of the house.

1625. Objections to metallic roofs. In general it may be observed, that till lately gardeners had a prejudice against metallic roofs. Of authors, who have avowed this, Abercrombie, Mean, and Nicol, may be mentioned; others have adopted a cautious neutrality, as M'Phail, Forsyth, Aiton, &c. Philosophical and amateur gardeners have generally approved of their introduction; among which may be named Knight, Sir George MacKenzie, Lodgdie, and others. We shall here, as briefly as possible, enumerate the objections to metallic roofs, which are expense, rust, breakage of glass, abdication of heat, and attraction of electricity.

Expense. Metallic houses are, in general, rather more expensive than wooden ones; but they admit more light and are more durable and elegant.

Rust. That all ordinary metals are liable to rust is undeniable. This objection cannot be got rid of. The reply is, balance against it the advantages of light and durability; and take into consideration that careful painting will in a great degree prevent it. Knight observes, if one third of the sum requisite to keep a wooden roof properly painted be expended upon an iron roof, no injury will ever be sustained from the liability of that to suffer iron rust. (Hort. Trans. v. 231.)

Breakage of glass. This is altogether denied, as respects cast or wrought iron at least, and if applicable at all, can only be so to copper or compound metallic roofs, where weakness produces a bending of the sash; or where corrosion or unequal expansion of improper mixtures of metals as iron cased with copper, occasions a twisting of the bar. Cast-iron or solid wrought-iron frames, have never been known to occasion the breakage of more glass than wood. The grand cause of the breakage of glass, arises in almost every case from glazing with broad laps. The expansibility of copper is greater than that of brass, and that of brass greater than the expansion of iron in the proportion of 95, 89, 00. (Young's Lect.) Consequently copper is above one third part more likely to break glass than iron; but when it is considered, that a rod of copper expands only one hundred thousandth part of its length, with every degree of heat, and that iron only expands the one hundred and sixty-six thousand six hundred and sixty-sixth part, the practical effects of our climate on these metals can never amount to a sum equal to the breakage of glass.

Abdication of heat. The power of metals to conduct heat is an objection, which, like those of rusting and additional expense, cannot be denied. The reply is, the smaller the bars, the less their power of conducting; and a thick coat of paint, and the covering of half the bar by the putty requisite to retain the glass, also lessens this power; it is true, they may be supplied by art, but, in the bright light, the grand advantage gained by metallic bars, cannot, by any human means, be supplied otherwise than by the transparency of the roof.

Attraction of electricity. To this objection it is replied, that if metallic hot-houses attract electricity, they will conduct it the ground, so that it cannot do any harm. Also that no instance can be produced of iron hot-houses having been injured by the effects of this fluid.

Subsect. 4. Glazing of Hot-house Roofs.

1626. Glazing was formerly performed with the very worst description of glass, called green glass; and accordingly, Adanson, in 1710. recommends the adoption of Bohemian glass, then the best in Europe, but now equalled by our best crown or patent crown tables. If, as Bouguer has shown, one fortieth part of the light which falls perpendicularly on the purest crystal is reflected off, or does not pass through it, it may safely be
asserted, that green glass reflects off more than three fourths. Economy, as to the quality of glass, therefore, is defeating the intention of building hot-houses, which is to imitate a natural climate in all the qualities of light, heat, air, water, earth, &c. as perfectly as possible. Without a free influx of light, the sickly pale etiolated appearance of plants is more painful than agreeable to the eye of any who take an interest in the vegetable kingdom. As the panes or pieces of glass employed in hot-house roofs lap over each other, the air which enters by the lap, when uneven glass is employed or careless glazing performed, no doubt, suggested the idea of closing the lap with lead or putty. But both these modes being found to prevent the water which collects on the inner surface of glass roofs, from escaping by the outside surface, gave rise, first, to partially closing the lap; and subsequently to various forms of panes, and descriptions of laps, of which the principal are as follow.

1627. **Common sash-glazing** is performed by even the best hot-house builders with a lap of from one fourth to three fourths of an inch; but by the great majority of glaziers, with a full inch lap. The objection to this mode is, that the broader the lap, the greater the quantity of water retained in it by capillary attraction; and when such water, through a deficiency of heat in the house, is frozen, the glass is certain of being broken. But supposing this breakage not to take place, the broader the lap, the sooner it fills up with earthy matter, forming an opaque space, both injurious by excluding light, and unpleasing because imperfect: or if the lap is to be puttied, the opacity is the same. The accidental filling up of such spaces (when not puttied by art) with dust and earthy matter, is what prevents them from being broken, by excluding the water in a great degree. Where the lap is not more than one fourth of an inch, it may be puttied without a very disagreeable effect. The rectangular pane is the only form which can with propriety be admitted in curvilinear roofs; and the most approved practice as to the lap, whether in roofs or common sashes, is never to make the lap greater than the thickness of the glass, and not to close it with putty. It is extremely difficult to get glaziers to attend to this; but by employing superior workmen, and obliging them to remove every pane which shall project over the other more than one sixteenth of an inch, the thing may be accomplished. This is not only the most elegant of all modes for a curved roof, or indeed for any other, but the safest for the glass, which is, we repeat, seldom broken by any other natural means than the expansion of frozen water retained between the laps. It must not be forgotten that this form is also by far the easiest to repair, and that no mode of puttying or closing a narrow lap with lead is of long duration.

![Diagram](image)

1628. **Glazing with a leaden lap** (265. a) was formerly practised with a view of excluding the air by a more permanent material than putty. The sort of lap made use of, is that used by glaziers in lattice-work windows (fig. 266. a.) The panes being inserted in the grooves, formed in the edges of the lap, are of course all in one plane, and the water in running down either the outside or inside of the roof, must accumulate on the upper edge of each riband or cross-string of lead, and so penetrate between it and the glass, and drop on the plants in the house. This indeed forms the chief objection to the leaden lap, which is now deservedly exploded.

1639. **An improved form of lead lap** (fig. 266. b) consists in using slips of lead rolled so thin as not to be thicker than fine drawing paper, in connection with putty, and for the sole purpose of retaining it in its place. It is never allowed to project beyond the exterior edges of the glass, so that it readily permits the descent of the water. Its thinness renders it easily manageable, and the time employed in filling up such laps, when one man is stationed outside the glass and another within, is not much more than that occupied in glazing a roof with the common putty lap. Such lead laps may either have a small opening in the middle, or at the angles, and are equally applicable to any of the modes of glazing to be described. The lead is rolled to any width, and clipt or cut to the size wanted as used.
1630. The copper lap (fig. 265. c) is the invention of D. Stewart, and its origin may be recognised in the ess-shaped shred of lead introduced by glaziers between newly glazed panes, to retain them in their places (fig. 265. d). The lap is drawn through graduated moulds till at last it is brought into the shape of the letter es compressed. It adds greatly to the strength of glazing, by giving each pane a solid firm bearing on the upper and lower edges, and by preventing water from lodging between the panes. Where the sashes are flat, however, it occasions droppings of condensed water on the plants, against which there is a general prejudice among gardeners; and it has been alleged, that the drip from copper becomes in a few years poisonous from the partial oxidation of the metal. In steep roofs, however, this objection does not hold, and there remains in such cases only the objection of the opacity produced by the lap. It has been used in the large conservatories at East Sheen and Woodlands; but appears to us much too opaque for hot-house roofs, and only adapted for skylights in common buildings. If so much light can be spared as is lost by these laps, it would be better to increase the number of sash-bars, by which the panes would be smaller, and consequently stronger and less expensive, and no metallic lap would be wanting. It is now entirely or nearly out of use.

1631. Fragment glazing (fig. 265. b). This is the primitive mode adopted by nurserymen and market-gardeners, before it was supposed that the productions raised under glass would pay for any better. In steep roofs it answers nearly as well as any other mode in respect to keeping out rain and air, but as somewhat greater lap is required in these crooked or undulated pieces of glass, a flat roof is liable to be covered by dark lines, formed by the lodging of earthy matter in the laps or interstices. Where the bars are not placed more than six or seven inches asunder, centre from centre, this method is much more economical than any other; and is therefore useful for such country-nurserymen or market-gardeners as have not, like the nurserymen of London, the opportunity of purchasing the hot-houses of decayed gentlemen or bankrupts; and consequently are obliged to build and construct every part ab origine.

1632. In rhomboidal glazing (fig. 265. c), the panes are in the form of rhomboids, the advantage of which is, that the water runs rapidly to the lower angle, and passes off both inside and outside along the bar; and what is retained by capillary attraction, is alleged to be so small as not to have the power of breaking the glass.

1633. Perforated shield glazing (fig. 265. d). This is a supposed improvement on the last described mode, which it would be, were it not that by the perforation in the upper part of the shield as it is called, the dexter and sinister chiefs are liable to be broken off; and by the prolonged accumulation of its base, it is rendered obnoxious to the same casualty in the nombril point.

1634. Entire shield glazing (fig. 265. e). This plan has been used by Butler, a London hot-house builder; but it does not seem either to merit or obtain general adoption. It is difficult, indeed, to conceive what are the arguments in its favor beyond that of strength, with a very great loss of light, which may surely be better obtained by Stewart’s lap.

1635. Curvilinear lap glazing (fig. 265. f). This mode appears, unless on very flat roofs, preferable to the common square mode, because the curve has a tendency to conduct the water to the centre of the pane. If the lap is broad, however, the globule retained there by attraction is situated precisely in the point where it is calculated to do most mischief, being in fact as a power on the end of two levers. When the lap is not more than one sixteenth of an inch, no evil of this sort can happen; it also happens less frequently for the first few years after putting the lap, and leaving a small opening in the centre for the water to escape. In time, however, according as the house has been used, the putty begins to decay, it becomes saturated with water, and during frost, whenever the temperature of the house is inadequate to prevent this water from freezing, the panes are certain of being broken. It can hardly be too often impressed on the mind of the gardener, that putting or otherwise filling up the lap is in no case requisite, if care be taken in the glazing to use flat glass, and never to let the lap exceed one fourth, or fall short of one sixteenth of an inch. This is now rendered the more easily practicable since the invention of a variety of glass called patent crown glass, and which, purchased in panes fit for hot-houses, is hardly more expensive than the other. It may be added, that taking all circumstances into consideration, and especially that of repairs, the common rectangular pane of a small size is, according to common consent, decidedly the best.

1636. Reversed curvilinear glazing (fig. 265. g) is a method of throwing the water of condensation on the bars, so as to carry it off by their means, and, if possible, prevent it from dropping in the house.

1637. Anomalous surfaces can only be glazed by throwing the panes into triangles, and by no other manner, unless by annealing and bending the glass, because these is the greatest number of points that will touch a globular surface in one plane. By adopting triangular panes the most singular-shaped roofs may be glazed as perfectly as the simplest forms of surface.
1638. Though the making of putty be hardly within the gardener's province, yet it is fitting he should know that there are several sorts, of which the following are the principal:

Soft putty, being a well-wrought paste of flour of whitening and raw linseed-oil;
Hard putty, composed of whitening and boiled linseed-oil;
Harder putty, in which a portion of turpentine, or what is called, drying, is introduced; and the
Hardest putty, composed of oil, red or white lead, and sand. The first is the most durable of all, because it forms an oleaginous coat on the surface, but it requires a longer time for drying. The hard sorts are apt to crack, if not soon well painted; and the hardest of all, though it appears to be impenetrable, and of the greatest durability, yet renders it difficult to replace a pane when broken. It seems, therefore, quite unfit for hot-houses. Much depends on well working the putty some days before it is to be used; and in general, that putty which has been ground and wrought in a putty-mill is to be preferred.

1639. The best sort of paint for hot-houses is that which, for the last twenty years, has been known by the name of anti-corrosion, which is composed chiefly of the powdered scoriae of the lead-mines of Col. Beaumont, near Hexham. There are other sorts, which are called anti-corrosive and impenetrable paints; but they have not been long enough in use to enable us to recommend them. It may be a sufficient recommendation of the anti-corrosion to state, that it is used in government works, and especially on all cast-iron erections, by Rennie, Telford, and others. As to the color of paint, or washes of any sort, for the walls or interior of hot-houses, it is almost unnecessary to observe, that as light is the grand object, white is to be preferred.

SUBSECT. 5. Walls and Sheds of Hot-houses.

1640. Walls of some sort are necessary for almost every description of hot-house, for even those which are formed of glass on all sides are generally placed on a basis of masonry. But as by far the greater number are erected for culinary purposes, they are placed in the kitchen-garden, with the upper part of their roof leaning against a wall, which forms their northern side or boundary, and is commonly called the back wall, and the lower part resting on a low range of supports of iron or masonry, commonly called the front wall. Behind the back wall a shed is commonly formed, and under this is placed the furnace, the fuel to be used therein, and other materials or implements connected with the culture or management of the hot-house.

1641. The parapet, or front wall, of hot-houses comes first in order. Where upright sashes are used, there are generally brick walls, either carried up solid from the foundation, or built on piers, according as it may be desirable to have the roots of the plants within pass through to the soil without, or not. In the case of fixed roofs, that part of the wall which is above ground is formed with horizontal openings, to which opaque or glazed shutters are fixed, opening outwards for the purpose of admitting air. A recent improvement on parapets consists in forming them of cast-iron props or pillars (fig. 267.), which are placed on a basis of two or three bricks (c, c), three or four feet under the surface: to these props, top and bottom rails are fitted, which are rebated to receive a shutter. (fig. 268.) The wall-plate (a, b, figs. 267, & 268.), which receives the ends (d) of the rafters or sash-bars, forms also a gutter for carrying off the water of the roof, externally (a), and the condensed water internally (figs. 267, & 268. b).

1642. Where the roof is moveable on the polyprosopic plan, no such shutters are required, and therefore the ends of the rafters may go at once three or four feet into the soil, according to the nature of the foundations, and rest on brick-work; the surface of the ground, and the lower edge of the lowest sash being united by a moveable plate, forming at once a gutter and a rest for the lower rail of the sash.
1643. **Holes for vine-stems (fig. 268. f, f).** In all parapets or front arrangements where vines are to be introduced from without, particular care must be had to provide for the withdrawing of the vines, even when their wood is of a considerable age and thickness. For this reason, where horizontal shutters are used, the lower styles or pieces against which they shut, should always be moveable; and, in general, it may be stated, that of the various modes for the introduction of the vine from without which have been adopted, that by cutting off a corner of the sloping or front sash, is the best; by this means, when the sash is opened, a vine of almost any size (fig. 269. a) may be taken out with ease. A piece of thin board or cork cut every year to fit the increasing diameter of the shoot is screwed to the wall-plate or lower style, as the case may be, and the vacuity, which must necessarily be left around the stem, is closed up with moss. When the vine is to be taken out by unscrewing the triangular board, and opening the sash, or shutter, a more than sufficient space for drawing out any ordinary-sized plant is obtained without the least trouble or chance of fracturing the shoots. It may be added, that in curvilinear ground plans, some exertion of design and nicety of workmanship is required in framing the horizontal shutters, so as they shall not twist, and also that they require in such cases to be hinged with what are called coach-hinges.

1644. **Glazed shutters (fig. 269.)** are preferred by some to an opaque panel, the utility of which must, of course, depend on the relative height of the pots or plants immediately within. The mode of opening such shutters, and keeping them open (fig. 270.), is perfectly simple.

1645. **The back wall** is in general straight or perpendicular, and carried up one or two feet higher than the glass, to shelter it from the north. (fig. 255.) Sometimes, however, it is bevelled or curved to meet the sun's rays. (fig. 261. b)

1646. **The back shed (fig. 256. a)** is naturally connected with the back wall, and in form and extent, is generally regulated more by its uses as a working-shed, than by the mere enclosure and covering of the fire-places and fuel, its original and legitimate objects. The width may be varied at pleasure, but seldom exceeds ten or twelve feet, and the height is generally seven or eight feet in the lower wall, and nearly of the same height as the back wall; but where opening shutters are formed in the back wall, for the purposes of ventilation, the upper angle of the shed-roof must be kept under the level of the shutters to save intricacy of contrivance. But as these shutters frequently do not communicate directly with the open air, but with passages under the shed-roof, or channels in the top of the back wall, the height of the shed may in such cases be made higher. In some cases, instead of shutters (fig. 270.), boards sliding in grooves, or a sort of Venetian blind, or which is best, flaps held close by a cord, pulley, and weight, are used; but the great heat of hot-houses is apt to warp and derange some of these contrivances. The essential part of the back shed, as respects the hot-house, is the situation for the furnace and fuel, or steam-apparatus, with which no other use to which it may be applied must be allowed to interfere. Sometimes back sheds are not enclosed, but supported on pillars, in which case they are used for fermenting tan, leaves, or dung, growing mushrooms on ridges of dung, holding pots, pease-sticks, and other similar purposes. Where the range of hot-houses is situated in the middle of the garden, great care must be taken, that it present nothing offensive, and that the sheds behind neither resemble a row of workshops, alms-houses, brickmakers' sheds, or cattle-hovels. An effectual way of preventing this, is by carrying up the walls of the sheds as high as the other walls, thus completely concealing their roofs.

**Subsect. 6. Furnaces and Flues.**

1647. **The most general mode of heating hot-houses is by fires and smoke-flues,** and on a small scale, this will probably long remain so. Heat is the same material, however produced; and a given quantity of fuel will produce no more heat when burning under a boiler than when burning in a common furnace. Hence, with good air-tight flues, formed of well burnt bricks and tiles accurately cemented with lime-putty, and arranged so as the smoke and hot air may circulate freely, every thing in culture, as far as respects heat, may be perfectly accomplished.

1648. **The hot-house fire-place, or furnace,** consists of several parts: a chamber, or oven, to contain the fuel, surrounded by brick-work, in which fire-brick (a sort containing a large proportion of sand, and thus calculated by their hardness not to crumble by heat, &c.) is used; a hearth or iron grating, on which the fuel is laid; a pit or chamber in which the ashes drop from this grating, and iron doors to the fuel-chamber and ash-pit.
1649. *The iron doors* admit of several varieties; but it does not appear that there is any great difference in the effect produced by the different plans of Nicol, Hay, Stewart, and others. A double door has the advantage of durability, of preserving heat, and of not so readily admitting cool air to pass *over* the fire; which air, of course, must be less heated, and consequently less capable of heating the flue than such as, entering from below, passes *through* it. The use of the ash-pit door is to act as a regulator to the current of air, or as a damper or suffocator.

1650. *Vacuities have been formed around furnaces,* and by communications between these and the open air, and an air-flue in the house, a stream of heated air has been introduced; but this air is so little at the command of the gardener; is so dried up or burnt, as the phrase is, that is, mixed with offensive gases from decomposed water, burned oil, iron, sulphur, or very fine dust; and so liable to be mixed with smoke, that such plans are now generally laid aside. Vacuities, however, are frequently formed round furnaces, and along the first or six feet of the flue, in order to temperate the heat in that part; but such vacuities rarely have any communication with the air of the house. Where a house of considerable length and volume is to be heated, it is generally deemed better to increase the number of furnaces than to increase their size, or have recourse to air-flues; for when the latter practice is resorted to, they are necessarily projected so far into the shed, or otherwise kept back from the house, that a great part of the heat is lost in the mass of brick-work which surrounds them. Small furnaces, on the contrary, may be built in great part under the walls or door of the house. In countries where turf, wood, or inferior coal, is used for fuel, the chamber of the furnace must be large; on the contrary, where the best coal, cinders, charcoal, or coke (the three last, the best of all fuel for hot-houses, as having no smoke), is used, they may be made smaller in proportion to the different degrees of intensity of the heat produced by these different materials. In fixing on the situation of furnaces, care must be taken that they are always from one to two feet under the level of the flue, in order to favor the circulation of the hot air and smoke, by allowing it to ascend.

1651. *A small lime-kiln* (fig. 271. a) is in some places constructed or fixed over hot-house furnaces for burning lime; and when the heat, which passes through the limestone, is made to enter the flues (e), it is evident a real benefit must result from the practice, as the heat applied to the burning of the lime in the common way escapes in the atmosphere. The grate or fuel bars (d) are contrived to draw out, by means of a grooved frame (c), so that when the lime is burned, it then drops into the ash-pit (b).

1652. *As to the size of hot-house fire-places,* the door of the furnace may be from ten inches to one foot square; the fuel-chamber from two to four feet long, from eighteen inches to two feet wide, and of the same dimensions as to height. Every thing depends on the kind of fuel to be used. For Newcastle coal, a chamber of two feet long, eighteen inches broad, and eighteen inches high, will answer as well as one of double the size, where smoky Welsh or Lancashire coal is to be used. Various contrivances, as hoppers, horizontal wheels, &c. have been invented for supplying fuel to furnace-fires without manual labor, and especially during night; but from the nature of combustion, and the common materials used in this country to supply it, no effectual substitute has yet been discovered. If wood or charcoal, or even cinders or coke were used, there would be a greater chance of such inventions succeeding, but we do not think ourselves warranted in detailing any of them.

1653. *The modes of constructing flues are various.* The original practice was to build them on the naked earth, like drains or conduits; or in the solid walls of the backs and fronts of the pits, like the flues of dwelling-houses. The first improvement seems to have been that of detaching them from the soil by building them on flag-stones, or tiles supported by bricks; and the next was, probably, that of detaching them from every description of wall, and building their sides as thin as possible. A subsequent amelioration consisted in not plastering them within, but in making their joints perfect by lime-putty, by which means the bricks were left to exert their full influence in giving out the heat of the smoke to the house.
1654. The sides of common flues are commonly built of bricks placed on edge, and the top covered by tiles, either of the full width of the flue outside measure, or one inch narrower, and the angles filled up with mortar, which Nicol prefers, as nearer. Where a stone that will endure fire-heat without cracking is found to be not more expensive than tiles, it is generally reckoned preferable, as offering fewer joints for the escape of the smoke. Such stones are sometimes hollowed on the upper surface, in order to hold water for the benefit of plants in pots, or for steaming the house.

1655. Broad and deep flues, agreeably to the Dutch practice, have been recommended by Stevenson (Caled. Mem.) ; that of making them narrow and deep, agreeably to the practice in Russia, is recommended by Oldacre, gardener to Sir Joseph Banks, and that of using thin bricks (fig. 272.) with thick edges, by S. Gowen (Hort. Trans. iii.) In Gowen's flues, the section (fig. 273. a) shows less materials than any other brick flue, the covers (b) and the side wall bricks (c) being quite thin, the base requisite for building the latter on one another being obtained by the thickness of their edges (d, e), which is equal to that of common bricks.

1656. Can-flues (fig. 274.), long since used by the Dutch, imbedded in sand, and for the last fifty years occasionally in England, are sometimes employed. They consist of earthen pipes, straight (a), or rounded at the ends for returns (b), and joined together by cement, placed on bricks (c). They are rapidly heated, and as soon cooled. None of the heat, however, which passes through them, can be said to be absorbed and lost in the mass of enclosing matter, as Knight and Sir Joseph Banks (Hort. Trans.) assert to be the case with common flues. They are only adapted for moderate fires, but judiciously chosen, may frequently be more suitable and profitable than common flues; as, for example, where there are only slight fires wanted occasionally; or where there is a regular system of watching the fires, in which case, but not otherwise, the temperature can be regulated with sufficient certainty.

1657. The embrasure flue (fig. 275.) is the invention of Sir G. Mackenzie, and is by him strongly recommended, as exposing a greater heated surface in proportion to its length. (Hort. Trans. vol. ii. p. 175.)

1658. Cast-iron flues have also been recommended on account of their durability, but unless they were to be imbedded in sand, or masonry, they are liable, in an extreme degree, to the same objections as can-flues. A triangular cast-iron flue, to be coated over with a mixture of one part clay and three of sand, is recommended for trial by Sir G. Mackenzie. (Hort. Trans. v. 216.) For our part we cannot perceive a single circumstance in favor of its adoption.

1659. The best sort of flues, after all that has been said on the subject, is, in our opinion, the common form, built of thin well burned bricks neatly jointed, with the bottom and top of tiles, and no plaster used either inside or outside. Where only one course of a flue can be admitted the broader it is the more heat will be given out as it proceeds, and as a consequence, one extremity of the space to be heated will be hotter than the other; a return or double course of a narrow flue is, therefore, almost always preferable to one course of a broad flue. With respect to the embrasure flue, flues with iron tubes, or iron covers, and various others that have been recommended or described in recent volumes of the Horticultural Society's Transactions, they are liable, in our opinion, to great objections, and chiefly to produce sudden excesses of heat, and in general as tending to extremes of temperature.

1660. The size of flues is seldom less than nine inches wide, by fourteen or eighteen inches high inside measure, which suits a furnace for good coal, whose floor or chamber is two feet long, eighteen inches wide, and eighteen inches high. According as the object varies, so must the proportion both of furnaces and flues. (Designs for Villas, &c. 1812;
Hort. Trans. vol. iv.) The furnaces from whence the flues proceed, are generally placed behind the back wall, as being unsightly objects; but in point of utility, the best situation is at the end of the front wall, so as it may enter the house, and proceed a considerable length without making an angle. A greater utility, however, is here given up for fitness; it being more fitting in a gentleman's garden that something should be sacrificed to neatness, than that all should be sacrificed to profit.

1661. The direction of flues, in general, is round the house, commencing always within a short distance of the parapet, and after making the course of three sides, that is, of the end at which the fire enters, of the front, and of the opposite end, it returns (in narrow houses) near to or in the back wall, or (in wide houses) up the middle, forming a path; and in others, immediately over or along side of the first course. In all narrow houses this last is the best mode.

1662. The power of flues depends so much on their construction, the kind of fuel, the roof, mode of glazing, &c. that very little can be affirmed with any degree of certainty on this subject; 3000 cubic feet of air is in general enough for one fire to command in stoves or forcing-houses; and 5000 in lean-to green-houses. In houses exposed on all sides, 2000 cubic feet is enough in stoves, and 3000 cubic feet for green-houses. The safest side on which to err is rather to attach too little than too much extent to each fire, as excessive fires generally force through the flues some smoke or mephitic air; and besides produce too much heat at that part of the house where the flue enters.

1663. Dampers, or valves, are useful in flues and chimneys, both in case of accident and also to moderate the heat, or in case of one furnace supplying two flues, to regulate the passage of smoke and heat. For general purposes, however, the ash-pit door is perfectly sufficient. The damper, and furnace, and ash-pit doors ought seldom to be all shut at the same time, as such a confinement of the hot air of the flue is apt, owing to its expansion by increased heat from the hot masonry, to force some of it through the joints of the flue into the house.

1664. Chimney-tops are generally built on the coping of the back wall, and sometimes ornamented with mouldings, and even disguised as vases. Where there are only one or two to a conservatory or other house of ornament, these last modes may be allowable; but in culinary ranges, it appears to us an unsuitable application of ornament either to form on the stone or brick chimneys many mouldings, or to disguise them, as urns or vases. When these last are to be adopted, cast-iron presents abundant facilities of economical execution. There is a four-sided composition-stone chimney-pot recently come into use near London, which will answer extremely well till it becomes so common as to be reckoned vulgar. Sometimes the flues are carried under ground to some distance from the hot-house, and the chimney carried up in a group of trees, or otherwise concealed. This practice is suitable to detached buildings formed of glass on all sides.

Subject. 7. Steam Boilers and Tubes.

1665. Steam affords the most simple and effectual mode of heating hot-houses, and indeed large bodies of air in every description of chamber, for no other fluid is found so convenient a carrier of heat. The heat given out by vapor, differs in nothing from that given out by smoke, though an idea to the contrary prevails among gardeners, from the circumstances of some foul air escaping into the house from the flues, especially if these are over-heated or over-watered; and from some vapor issuing from the steam-tubes when these are not perfectly secure at the joints. Hence flues are said to produce a burnt or drying heat, and steam-tubes a moist or genial heat, and in a popular sense this is correct for the reasons stated. It is not, however, the genial nature of steam heat which is its chief recommendation for plant-habitations, but the equality of its distribution, and the distance to which it may be carried. Steam can never heat the tubes, even close to the boiler, above 212 degrees, and it will heat them to the same degree, or nearly so, at the distance of 1000, 2000, or an indefinite number of feet. Hence results the convenience of heating any range or assemblage of hot-houses, however great, from one boiler, and the lessened risk of over or insufficient heating at whatever distance the house may be from the fire-place. The secondary advantages of heating by steam are the saving of fuel and labor, and the neatness and compactness of the whole apparatus. Instead of a gardener coming to attend to a dozen or more fires, he has only to attend to one; instead of ashes, and coal, and unsightly objects at a dozen or more places in a garden, they are limited to one place; and instead of twelve paltry chimney-tops, there is only one, which being necessarily large and high, may be finished as a pillar so as to have effect as an object; instead of twelve vomitors of smoke and flakes of soot, the smoke may be burned by using Parkes's or some other smoke-consuming furnace. The steam-tubes occupy much less space in the house than flues, and require no cleaning; they may often pass under paths where flues would extend too deep; there is no danger of steam not drawing or circulating freely as is often the case with flues, and always when they are too narrow or
too wide, or do not ascend from the furnace to the chimney; steam is impelled from the boiler and will proceed with equal rapidity along small tubes or large ones, and descending or ascending. Finally, with steam, insects may be effectually kept under in hot-houses, with the greatest ease, by merely keeping the atmosphere of the house charged with vapor from the tubes for several hours at a time.

1666. The disadvantages of steam as a vehicle for conveying heat to hot-houses are few. On a small scale it is more expensive than the mode by flues, and more trouble is required to attend to one boiler than to one or even two or three furnaces. These are all the disadvantages we know of. It has been stated by some that steam draws up or etiolates botanic plants, and lessens the flavor of fruits; but we are inclined to consider such effects, when attendant on plants or fruits in houses heated by steam, as resulting from some deficiency of management in other points of culture.

1667. The boilers used to generate steam are formed of cast or wrought iron, or copper, and of different shapes. Wrought-iron and an oblong form are generally preferred at present, and the smoke-consuming furnace most approved is that of Parkes.

1668. The tubes used for conveying steam are formed of the same metals as the boilers; but cast-iron is now generally used. Earthen or stone ware tubes have been tried; but it is extremely difficult to prevent the steam from escaping at their junctions. The tubes are laid along or around the house or chamber to be heated, much in the same manner as flues, only less importance is attached to having the first course from the boiler towards the coldest parts of the house, because the steam-tube is equally heated throughout all its length. As steam circulates with greater rapidity, and conveys more heat in proportion to its bulk, than smoke or heated air, steam-pipes are consequently of much less capacity than smoke-flues, and generally from three to six inches diameter inside measure. Where extensive ranges are to be heated by steam, the pipes consist of two sorts, mains or leaders for supply, and common tubes for consumption or condensation. Contrary to what holds in circulating water or air, the mains may be of much less diameter than the consumption pipes, for the motion of the steam is as the pressure; and as the greater the motion, the less the condensation, a pipe of one inch bore makes a better main than one of any larger dimension. This is an important point in regard to appearance as well as economy. In order to procure a large mass of heated matter, M·Phail and others have proposed to place them in flues, where such exist. They might also be laid in cellular flues built as
cellular walls. (fig. 238.) The most complete mode, however, is to have three parallel ranges of steam-pipes of small diameter, communicating laterally by cocks. Then, when least heat is wanted, let the steam circulate through one range of pipes only; when more, open the cocks which communicate with the second range; and when most, let all the three ranges be filled with steam. This plan has been adopted by Messrs. Lod- diges at Hackney, and Messrs. Bailey in heating the hot-houses at Knowle and other places.

1669. As an example of the power and convenience of steam, as a medium of conveying heat to hot-houses, we may refer to the garden, mansion, and farm-yard of Edward Gray, Esq. of Harringay House, Hornsey, where ten large hot-houses, and the largest of them 550 feet from the boiler, have been heated in a masterly manner by Messrs. Bailey. There are for this purpose two boilers (fig. 276. a & b): one smaller than the other for mild weather, and when the whole of the forcing-houses are not in operation; and the other larger as a re- serve boiler in case of accident, as an accessory power in extremely severe weather, or for use alone in cold weather. A main from these boilers heats in succession two graperies (c, d) two pineries (e, f), a peach-house (g), strawberry-pit (h), plant-stove (i), grapeery (k), green-house (l), conservatory (m), and a mushroom-house, in all upwards of 50,000 cubic feet of air. In addition it supplies a steam-apparatus in the farm-yard (n); and it would also heat the mansion (o) if required. The boilers to this steam-apparatus are on the most approved construction: they are fitted up with furnaces for consuming the smoke (p), have safety-valves (q), a supply-cistern (r), and chimneys (s) sufficiently high to pre- vent what smoke or contaminated air may pass off by them from injuring the garden. So effectually is heat carried by steam, that at the extreme distance from the boiler (t) a thermometer applied to the steam-pipe will rise to within two degrees of what it will stand at close to the boiler. The whole is a most masterly performance.

1670. Pipes of hot water have been proposed to be circulated through hot-houses by Knight (Hort. Trans. vol. iii.); the plan was tried many years ago by the late Gould, gardener to Prince Potemkin, in the immense conservatory of the Tauridian palace at Petersburgh. There, however, pumps were employed to re-deliver the water to the boiler. It was adopted to a certain extent by Davis, a sugar-boiler in Essex; but it does not appear likely to become general. The only advantage proposed is, that should the boiler or steam-apparatus go wrong in the night-time, pipes filled with water would be longer of cooling than pipes filled with steam. It has been asserted in reply, that an appa- ratus capable of circulating hot-water, would be much more likely to go out of order than one adapted to circulate steam.

Subsect. 8. Trellises.

1671. Trellises are of the greatest use in forcing-houses and houses for fruiting the trees of hot climates. On these the branches are readily spread out to the sun, of whose influence every branch, and every twig and single leaf partake alike, whereas, were they left to grow as standards, unless the house were glass on all sides, only the extremities of the shoots would enjoy sufficient light. The advantages in point of air, water, pruning, and other parts of culture, are equally in favor of trellises, independently altogether of the ten- dency which proper training has on woody fruit-trees, to induce fruitfulness.

1672. The material of the trellis is either wood or metal; its situation in culinary hot- houses is against the back wall, close under the glass roof, or in the middle part of the house, or in all these modes. Sometimes it is in separate parts, and either fixed or moveable; and in some cases, though rarely, it is placed across the area of the house. Sometimes it is introduced or merely in arches, festoons, &c. The most general plan is to place it under the glass and at the distance of from ten to twenty inches from it, according to the length of the footstalk of the leaves of the plants to be trained.

1673. The back wall trellis was formerly in general use, and considered the principal part of the house for a crop; but that is now only the case in narrow houses. In many cases a trellis is still applied against the back wall for temporary crops, till the plants trained under the front glass trellis cover the roof; or for figs, which are found to succeed better than most trees under the shade of others.

1674. The middle trellis is generally recurvate so as not to exclude the light from the back wall. Sometimes it is horizontal for the same purpose, and sometimes it is omitted, and dwarf standards preferred in its room.

1675. The front or roof trellis generally extends under the whole of the roof, at a mo- derate distance (256. b) from it, according to circumstances. It is generally formed of wires stretched horizontally at 6 or 8 inches' distance, and retained in their places by being passed through wrought-iron trellis-rods proceeding from the parapet to the back wall, or the lower edges of the rafters, when formed in a manner adapted for this end.
1676. The fixed rafter-trellis consists ordinarily of three wires, which pass through the points of crosses (fig. 277.), in breadth from fourteen to eighteen inches, and which crosses are screwed to the under edge of the rafter; the first fixed at the plate of the parapet, and the last at the upper end of the rafter, and the intermediate ones at distances of from three to four feet.

1677. The moveable rafter-trellis consists of a rod bent parallel to the roof, with horizontal studs or rods, extending from 6 to 10 inches on each side, containing two collateral wires, the rod itself forming the third. This rod is hinged, or moves in an eye or loop, fixed either immediately above the plate of the parapet, or near the top of the front glass. It terminates within one or two feet of the back wall, and is suspended from the roof by two or more pieces of chain attached to the studs, the links of which are put on hooks attached to proper parts of the roof. Their advantage is chiefly in the case of very early forcing, when they can be let down two or three feet from the glass, and thus is lessened the risk of injury from frost. A whole sheet or tegument of trellis, if desirable, may be lowered and raised on the same general plan. (See the details, Hort. Trans. vol. iii.) Rafter-trellises are in general used only for such houses as are not chiefly devoted to vines; such as pineries, peach-houses, and sometimes green-houses.

1678. The secondary trellis is placed from six inches to eighteen inches behind the first, and is used for training shoots of the current year, while that nearest the light is devoted to such as are charged with fruit. In ordinary trellises, the wires are generally placed from nine inches to a foot asunder, in a horizontal direction; on the secondary trellis they are placed at double that distance.

1679. The cross trellis has been sometimes employed in peach-houses, and is strongly recommended by Sir George Mackenzie, in what he calls an economical hot-house. These trellises, however, unless kept very low, darken the house to such a degree as to prevent the ripening of fruits. They may be useful for nurserymen for training peaches or fig-trees for sale, but for culinary forcing are worse than useless. Sir G. M.'s house, though lauded by Dr. Duncan (Caled. Memoirs, vol. ii.), was soon obliged to be cleared of its cross trellises, and restored to the common form. The only houses where such trellises can be used with any reasonable prospect of advantage, are such as are placed south and north, and span-roofed, or glass on all sides. On these two or more lines of low trellis may be placed, and the plants will enjoy the forenoon's sun on one side, and the afternoon's sun on the other.

1680. The entrance to hot-houses is commonly at each end, and sometimes in the middle, either of which modes answers perfectly where the ground-plan is a parallelogram; but for any description of curvilinear house, the entrance is more commodiously made through a lobby at each end of the house, and which lobby is best formed behind the wall. When there are a number of curvilinear houses placed against one wall, one door in the wall between each will serve every purpose, and the whole will be at once elegant and commodiously connected. (fig. 252.)

Subsect. 9. Paths, Pits, Stages, Shelves, Doors, &c.

1681. The paths in hot-houses vary in direction, breadth, and construction. In general, one path runs parallel to the front, sometimes upon the front flue, but more generally beside it; at other times, as in peach-houses, it passes near the back wall, or through the middle of the house. In pineries and houses with pits, it generally surrounds these, and in green-houses it is commonly confined to a course parallel to the front and ends. Some of the most ornamental paths we have yet seen have been formed by Messrs. Bailey, of cast-iron plates, laid over steam-pipes, and so perforated as to form an elegant running pattern, or cast-iron carpet.

1682. The materials of which the path is composed in the case of some houses, are mere planks, or lattice-work, supported on cross pieces of timber, in order to admit the sun and air to the soil below; and not to indurate it by the pressure of feet. An improvement on this mode consists in using grated cast-iron plates, which are more durable, and may be set on iron stakes driven in till their tops are on a level, and at a proper height, &c. These gratings are also particularly preferable when the path is over a flue, not only as presenting a cooler surface to walk on than the covers of the flue, but also by readily admitting the ascent of the heat in the interspaces, and preventing the movement of the covers by the motion of walking. But the best material for a permanent path, as in green-houses, botanic stores, &c. is argillaceous flag-stone, and of this one of the best varieties is that obtained from Arbroth, and known by the name of Arbroath pavement. It is a light grey schistus, which rises in lamina of from three to six inches in thickness, and eight or ten feet square; requires very little work on the surface; and has the property of but very slightly absorbing moisture from the atmosphere, or from the
moist ground on which it may be placed. Thus, unless when watered on purpose, it always appears perfectly dry and agreeable, however moist the soil below. Where the paths in a house are on different levels, they are commonly united by steps; but an inclined plane, when not steeper than one inch in six, will generally be found more convenient for the purposes of culture and management; and if the slope is one in eight, it is more agreeable to ascend or descend than a stair.

1683. Pits, as applied to the interior parts of houses, are excavations, or rather enclosures, for holding bark or other fermentable substances. They should be formed so as the plants may stand at a moderate distance from the glass, which of course depends on the nature of these plants, whether dwarf bushy plants, as the pine, or taller, as palms and hot-house trees. They are generally surrounded by walls of brick, four or nine inches thick, or to save room, by plates of cast-iron, stone, or slate. Sometimes the slope of their surface approaches to that of the roof; but as, in this case, the tan or leaves in the course of fermentation, do not settle or compress regularly, the pots are thrown off their level, and therefore the more common way is to adopt a slope not exceeding 5°, or to form a level surface. Tan will ferment with all the rapidity necessary for bottom heat, if in a layer of two and a half or three feet thick, and therefore no tan-pits need exceed that depth. Those for leaves may be somewhat deeper. Heat from fire, or steam, or water, is sometimes substituted for that afforded by fermentable substances, and in these cases various forms of construction are adopted. For fire-heat, flues are made to circulate under a covering of pavement, on which sand, gravel, scoria, or sawdust, is placed to preserve a moist heat round the pots. An air-chamber is thus formed under the pit, from which the heated air may be allowed to escape, if desired, by upright tubes, with stops, as in the Chelsea garden, or small openings in the side walls of the pit, as at N. Kent’s, of Clapton, or as we suggested and executed at different places in 1804. (Tr. on Hoth. 8vo. Edin. 1804. Hort. Trans. vol. ii.) Another mode consists in filling the vacuities round the flues with loose stones (as in the Glasgow garden), flints, brick-bats, or large gravel. These materials, when once heated, retain their heat a very long time, and give it out slowly to the superincumbent mass of sand, gravel, or other media, in which the pots may be plunged. Sometimes soil is placed over this stratum of stone and gravel, and the plants inserted in the soil. Pines have been successfully grown in this way at Underley Park from our suggestions. (Tr. on Hoth. 8vo. Edin. 1804.; Tr. on Country Resid. vol. i. 1806.) Another, and very old method of heating pits by smoke is by forming a vault under them, building in a furnace and ash-pit door at one end, and a chimney at that opposite. This is the mode originally used in France and Germany. (Encyc. Method. in vol. d’Aratoire et Jardinage, art. Sorre.) Knight suggests the idea of building the walls of bark-pits cellular, and of admitting at their bottom a current of external air, to be heated in the cells, and issue in that state into the house. This he “feels confident” will save fuel, but as it would be at the expense of the heat of the bark or other fermenting material in the pit, it does not appear to us that any advantage would result from the plan. (Hort. Trans. vol. v. 246.)

1684. Pits may be heated by steam by substituting tubes for flues, and in the case of the vault, merely by introducing the steam-tube about the middle of the space, and omitting the chimney. Or the tubes may circulate at once in the tan, sand, or sawdust; or a vaulety may be formed not more than six inches deep, the whole width of the pit, covered by pierced oak boards, and the steam introduced there at proper intervals. All these and other plans have been tried by Butler, at Knowle, near Prescot, in 1791; Mawer, at Dalry, in 1795; Thomson, at Tynningham, in 1805; Gunter, at Earl’s Court, in 1818; W. Phelps, of Wells, in 1829 (H. Trans. v. 357.), and various other persons; accompanied, as was to be expected, by different degrees of success. A cistern of water of the size of the pit has been heated by steam, and left to give out its heat to the superincumbent materials of the pit, by Count Zuboff, at Peterburgh. We have seen cucumbers grown over a cistern in which the hot water from a distillery passed through. The result of all the attempts hitherto made to find a substitute for the heat of fermentable substances, as applied to pits in which pots are to be plunged, is not such as to warrant much deviation from the usual practice. But that bottom heat may be very generally dispensed with altogether, at least with ornamental plants, modern experience goes far to prove; and it is more likely that it will be given up altogether, and bottom moisture obtained by plunging the pots in gravel or scoria, than that methods so expensive, and attended with so much risk to the plants, will ever come into general use.

1685. Beds and borders in hot-houses are generally formed on the ground level, though sometimes raised above it. They are either composed of earth, for the direct growth of plants, or of gravel or scoria, in or on which to place pots. When the use of tan is given up, as in some plant-stoves, the tan-pits are filled with gravel, on or in which, the pots are set or plunged. Where heat and moisture are judiciously applied, this mode is found to succeed perfectly, as at the Comte de Vandés', Bayswater, and Messrs. Loddiges', Hackney.
1686. Shelves, excepting such as are placed near the ground, or almost close under the upper angle of the roof, are extremely injurious to the vegetation going forward in the body of the house by the exclusion of light. This consideration, therefore, must be kept in view in placing them; in some cases they are inadmissible, as in conservatories; in others, as in propagating-houses, the light they exclude can better be spared, than in fruiting or flowering departments. For forcing strawberries, they may be introduced under the roof in vine and peach-houses, and removed when their shade proves injurious, &c. The ordinary form is that of a flat board; but an improvement consists in nailing two fillets along its edges, and covering the board with a thin layer of small gravel or scoria. This preserves a cool genial moisture which keeps the earth pot moist, and lessens the effect on the earth of alternate dryings and waterings; and it also admits the more ready escape of water from the orifices in the bottoms of the pots. Some, in the case of forcing strawberries and French beans, have the fillets or ledges of the shelves so high as to contain two or three inches of water, by which means whole rows of pots can be inundated at one operation; but this is too indiscriminate an application of a material on which so much in the growth of plants depends.

1687. Stages are shelves in series rising above each other, and falling back so as their general surface may form a slope. They vary in form according to that of the house. The houses with shed roofs and opaque ends have merely a series of steps reaching from one end to the other; but wherever the ends are of glass, by returning each shelf to the back wall, due advantage is obtained from the light furnished by the glass ends. The addition of ledgement, or turned-up edges to each shelf, and the covering them with gravel, is, of course, as advantageous as in separate shelves, and surely more consonant with natural appearances, than leaving them naked like household, or book shelves. Shelves and platforms of stone are now very general, and found more congenial to the plants than dry painted boards.

SUBSECTION 10. Details for Water, Wind, and Renewed of Air.

1688. The reservoirs of water in hot-houses are commonly cisterns of stone or timber, lined with lead, or cast-iron troughs or basins. Sometimes, also, tanks are built in the ground, and lined with lead or cement. The cistern is sometimes placed in an angle, or other spare part of the house, and the water lifted from it at once with the watering-pots; but a more complete plan is to build it in an elevated part of the back wall, where it may have the benefit of the heat of the house, and whence pipes may branch off to different parts of the house with cocks, every 30 or 40 feet, for drawing supplies. Tanks and cisterns below the level of the front gutter may be supplied great part of the year from the water which falls on the roof; but more elevated cisterns must either be supplied by pumps, or elevated springs. The sources of supply, and the quality of the water must be taken into consideration before the situation of the cisterns are determined on. In all cases, there must be waste-boxes at the cocks, and waste-pipes from the cistern, to counteract the bad effects of leakage.

1689. Artificial rain. A very elegant plan has been invented and executed by Messrs. Loddiges, for producing an artificial shower of very fine rain in hot-houses, by conducting pipes horizontally along the roof, at the distance of six or eight feet, and having these pipes very finely perforated by a needle. According to the power of the supply, one or more pipes may be set to work at a time, and a very fine shower thrown down on the leaves of the plants with the greatest regularity. This has been done in one of the palm-houses of these spirited cultivators at Hackney, and for which a medal was voted to them by the Horticultural Society, in 1817. The following is a particular account of this apparatus. (Hort. Trans. vol. iii. p. 15.)

A leaden pipe of half an inch bore is introduced into one end of the house, in such a situation that the stop-cock, which is fixed in it, and which is used for turning on the supply of water, may be within reach: it is then carried either to the upper part, or the back of the house, or to the inside of the ridge of the glass framework, being continued horizontally, and in a straight direction, the whole extent of the house, and fastened to the wall or rafters, by iron staples, at convenient distances. From the point where the pipe commences its horizontal direction, it is perforated with minute holes, through each of which the water, when turned on, issues in a fine stream, and, in descending, is broken, and falls on the plants, in a manner resembling a gentle summer shower. The holes are perforated in the pipe with a needle, fixed into a handle like that of an awl; it being impossible to have the holes too fine, very small needles are necessarily used for the purpose, and in the operation great numbers are of course broken. The situation of the holes in the pipe, and the length of any given portion that may be required, and in this particular the relative position of the pipe, and of the stations of the plants to be watered, must be considered, in making the perforations. The holes are made, on an average, at about two inches' distance from each other, horizontally, but are somewhat more distant near the commencement, and rather closer towards the termination of the pipe, allowing thereby for the relative excess and diminution of pressure, to give an equal supply of water to each end of the house. A single pipe is sufficient for a house of moderate length: one house of Messrs. Loddiges, which is thus watered, is sixty feet long, and the only difference to be made in adapting the plan to a longer range, is to have the pipe larger. The reservoir to supply the pipe, must of course be so much above the level, as to exert a sufficient force on the water in the pipe, to make it flow with rapidity, as it will otherwise escape only in drops; and as too strong a power may be readily controlled by the stop-cock, the essential point to be attended to, in this particular, is to secure force enough. From the above it will be observed, that
some nicety is required in the arrangement and formation of the machinery; but it is only necessary to view the operation in Messrs. Loddiges' house, to be convinced of the extreme advantage and utility of the invention, when it is properly executed. (Sabine, in Hort. Trans. vol. III. p. 15.) We adopted this plan on a smaller scale in our erections at Bayswater, and the whole of the plants under the square dome (in Fig. 235.) were watered from a perforated pipe, which passed round the dome near its apex, and radiated from thence a very fine shower, which reached every part of the floor beneath.

1690. Wind in hot-houses has been attempted, or rather recommended to be attempted, by Dr. Anderson and others by means of fans. If any thing of this sort were desirable, the Eolian machine invented by B. Deacon, already mentioned (1599.) might be employed, either placed in the house, and kept in motion by human, or mechanical power, or placed at one end to force in or draw out the air. In a range of houses forming a circle or square, or any endless figure, a perpetual breeze might be readily produced in the following manner. Place under the floor, a powerful fan of the width of the house. Exactly over the fan, place a glass division across the house, and let the fan draw in the air through apertures in the floor on one side of the division, and give it out through similar apertures, or through tubes of any sort on the other. It is evident, a regular current would thus be produced, more or less powerful according to the size of the fan, and the rapidity of its motion.

1691. Ventilators, &c. The general mode of renewing the air, is by opening the sashes or doors of the house, in periods when the exterior temperature and weather is such as not to injure the plants within. The cool air of the atmosphere being then more dense than that of the house, rushes in till it cools down the air of the house nearly to an equilibrium with that without. The next mode most common, is that of having a range of boards hinged to oblong openings, in the lower and upper parts of the house, and generally in the front and back wall; those in the back wall opening to the south, or having the opening otherwise guarded, so as to prevent the rushing in of cold north winds. Sometimes these ventilators are made with a cylinder and fans to extract the air, and sometimes, as most generally, they are mere openings of small dimensions; but, in order to effect any circulation or renewal with this sort of ventilators, the opening must have an area of two or three feet, and there must be a considerable difference of temperature between the air of the house and the open air.

1692. To effect the renewal, or cooling down the air, without manual labor, some contrivances have been adopted besides the automaton gardener of Kewley already described. (Fig. 217.) Dr. Anderson and J. Williams made use of oblong bladders made fast at one end, and with the other attached by means of a cord to a moveable pane or small sash. The bladder being filled with air at the common temperature allowed for the house, and hermetically sealed, the window remains at rest; but as the air of the house becomes heated, so does that of the bladder, which consequently swells, and assumes the globular form, its peripheries are brought nearer together, and of course the sash or pane pulled inwards. In a small house this scheme may answer perfectly well for the prevention of extreme heat. Another mode is by using a rod of metal, such as lead, of the whole length of the house, and one end being fixed to the wall, on the other is attached a series of multiplying wheels, the last of which works into one, which in various ways may open valves or sashes. As the expansion of lead is considerable, the effect of twenty degrees of increase with proper machinery, might perhaps guard against extremes, as in the other case. A column of mercury, with a piston-rod and machinery attached, has also been used, and a ring on a barometrical principle is suggested by Silvester; but the only complete mode is that of Kewley. For details at greater length on all the departments of the construction of hot-houses, see Remarks, &c. 4to. 1817.

Sect. IV. Mushroom-houses.

1693. The mushroom-house is a genus of plant-habitation, which differs from the others in requiring very little light. The simplest form of the mushroom-house is that of an open shed or roof, supported on props, for throwing off the rain, and protecting from perpendicular cold. Under this, the mushrooms are grown on ridges, covered by straw, &c. to maintain the requisite temperature.

1694. The fixed mushroom-house (Fig. 278.) is an improvement on the shed, by being better calculated for growing them in winter. Provided it be placed in a dry situation, the aspect, size, proportions, doors, or windows, are of little consequence. To be suffi-
efficiently warmed by one fire in winter, it should not contain more than 10,000 cubic feet of air. As mushrooms will not thrive without some light, and at all events require air, it ought to have two or three windows or valves for these purposes.

1695. The German mushroom-house (figs. 279, 280 & 281.) It is a common practice with German gardeners to grow mushrooms on shelves, and in pots and boxes, placed behind stages, or other parts of their forcing-houses otherwise unoccupied. (Dietrich's Gärtner's Lexicon; Ransleben's Brieffe, &c.) This practice was carried to England by Isaac Oldacre, who thus describes the sort of house adapted for the German practice. "The outside walls (G, H, figs. 279, 280.) should be eight and a half feet high, for four heights of beds, and six feet and a half for three heights, and ten feet wide withinside the walls; this is the most convenient width, as it admits of a set of shelves three feet and a half wide on each side; and affords a space through the middle of the house, three feet wide for a double flue and walk upon it. The wall should be nine inches thick, and the length of the house as it may be judged necessary. When the outside of the house is built, make a floor or ceiling over it (as high as the top of the outside walls) of boards one inch thick, and plaster it on the upper side (s, c) with road-sand well wrought together, one inch thick (this will be found superior to lime), leaving square trunks (f) in the ceiling, nine inches in diameter, up the middle of the house, at six feet distance from each other, with slides (s) under them, to admit and take off air when necessary; this being done, erect two single brick walls (v, v), each five bricks high, at the distance of five feet and a half from the outside walls, to hold up the sides of the floor-beds (a, a), and form one side of the air-flues (l, u, tu), leaving three feet up the middle (t x t) of the house for the flues. Upon these walls (v, v) lay planks (v v) four and a half inches wide and three inches thick, in which to mortise the standards (k) which support the shelves. These standards should be three inches and a half square, and placed four feet six inches asunder, and fastened at the top (k, k), through the ceiling. When the standards are set up, fix the cross bearers (i, n, i n), that are to support the shelves (a, a), mortising one end of each into the standards (i), the other into the walls (n). The first set of bearers should be two feet from the floor, and each succeeding set two feet from that below it. Having thus fixed the uprights (k, k), and bearers (i n), at such a height as the building will admit, proceed to form the shelves (a, a) with boards an inch and a half thick, observing to place a board (d, d), eight inches broad and one inch thick, in the front of each shelf, to support the front of the beds. Fasten this board on the outside of the standards, that the width of the beds may not be diminished. The shelves being complete, the next thing to be done is the construction of the flue (P, fig. 281.), which should commence at the end (L) of the house next to the door, run parallel to the shelves the whole length of the house, and return back to the fire-place, where the chimney (S) should be built, the sides of the flue inside to be the height of four bricks, laid flat-ways, and six inches wide, which will make the width of the flues fifteen inches from outside to outside, and leave a cavity (l u, figs. 279, 280.) on each side, betwixt the flue and the walls that are under the shelves, and one (x y) up the middle, betwixt the flues, two inches wide, to admit the heat into the house from the sides of the flues. The middle cavity (x y) should be covered with tiles, leaving a space (h) of one inch betwixt each tile, for the admission of the heat. The top of the flue, including the covering, should not be higher than the brick walls that form the front of the floor-beds. The reason why the sides of the flues are recommended to be built stronger than usual, is, because they support the walk. The walk itself is formed by three rows of tiles, the outside rows making the covering of the flues, and those of the centre row are what cover the middle cavity (x y), as above mentioned; the outside cavities (l u) of the flue are left open, the tiles which are placed over the flues being laid so as not to cover these.
cavities, which allows the heat of the sides of the flues to rise upwards." (Oldacre, in Hort. Trans. vol. ii.)

Sect. V. Cold Plant-habitations.

1696. Cold plant-habitations, though seldom or never erected, yet deserve to be mentioned as resources under certain circumstances. These circumstances may be, a desire to cultivate the alpine plants of Europe in tropical climates, or to cultivate the mosses and ferns of the north of Europe in its more southern countries.

1697. The principle on which a cold house can be constructed in a warm climate must either be that of the exclusion of the heat by coverings or envelopes; or the abdution of heat by evaporation or contact with cold bodies. Heat will be, to a certain extent, excluded, by forming the house in the ground; by excluding the sun's rays from its roof; by a high wall on three sides, leaving only an opening in the middle of the north side; and by a double or treble roof of glass to the excavation. A house to be cooled by evaporation may also be sunk in the ground; or it may be raised above it, shaded from the sun, and over it may be supported a number of shower-pipes (1689.), which, by producing a gentle and continual rain on the glass roof and stone or other sides of the house, would draw off much heat by evaporation. Enclosing it by a line of powerful jets d'eau would effect the same purpose. To produce cold by abdution, the house might be sunk; its floor supported on pillars; and its sides and bottom kept in contact with a running stream; or, if it could be afforded, ice renewable as it melted. These hints are sufficient to show how cold plant-habitations may be formed in any climate: to enter more at length on the subject would be useless, in a work calculated chiefly for the climate of Britain.

CHAP. III.

Edifices used in Gardening.

1698. Edifices of different kinds are required in gardening, for carrying on operations, for retaining or preserving materials and products, and for recreative or decorative purposes. We shall consider the leading genera in the order of economical, anomalous, and decorative edifices. In all of these, the details of construction belong to civil architecture; but the design of the greater part ought to be regulated by the judgment of the gardener or garden-architect.

Sect. I. Economical Buildings.

1699. Economical buildings are chiefly dwellings, store-rooms, and working-places, entrance-lodges, and buildings for procuring or retaining water.

1700. The head-gardener's dwelling-house, in small places, often assumes the character of porter's lodge to the gate or entrance; or is placed in some point of the grounds requiring protection. In all cases it should be near to the garden, and if forcing is carried on, the nearer it is placed to that department the better. Sometimes it is placed in the back sheds, but that is an unwholesome situation; such sheds fronting the direct north, and without a single opening to the south, east, or west, are entirely excluded from the sun, excepting during a few mornings and evenings in summer. A small enclosure, near the forcing-department, and, if possible, on rising ground, so as to command a view of at least that part of the garden, is to be preferred. With respect to accommodation, no dwelling in this country, for a servant expected to do his duty, ought to contain less on the ground-floor than a kitchen, back-kitchen, and parlor; on the floor above that, at least two bedrooms, with closets, and other requisite appendages, internal as well as external. This will suit a prudent man and his wife, not in circumstances to keep a maid, or to produce a numerous offspring. But for such as afford to keep a servant, or have, or deem it right to have, a large family, or persevere without thinking any thing about
the consequences in generating one child after another, more bedrooms will be necessary, and a larger parlor and kitchen. As a gardener, in common with other domesticated servants, is liable to be removed from the house he occupies at a short notice, and without any reference to his having, or being able to procure another, it follows, as a matter of justice, that what are called house-fixtures should be provided by the master. Water should be conducted to a pump fixed in the back-kitchen; a furnace and boiler for washing affixed; a proper range, with oven, &c. dressers, tables, shelves, &c. in the principal kitchen; grates, and such closets and clothes-presses placed in the parlor and other rooms, &c. as the occupier would place there, if he held the house on lease. In general, we may observe that a master has seldom occasion to repent making his servants’ abode comfortable, and even rather agreeable and elegant, than otherwise. A master of a well-regulated mind, indeed, will be anxious to effect this, as far as lies in his power, for every portion of animated nature under his protection.

1701. The gardener’s office is necessarily omitted in small places; but it is an essential requisite wherever several men are kept. It should, if possible, adjoin the dwelling, and be connected with the seed-room, fruit-room and cellar, root-cellar, tool-house, and gardener’s lodge. The furniture or appendages to this room are the writing-desk; a bookcase, containing a small library, to be let out to the men; a map of the garden, and of all the grounds under the master’s care; a herbarium press, and a cabinet for such specimens of plants as the gardener may find it useful to dry for his own use, or, as often happens, for that of his family; a drawing-board and T square; a board to be used when new grounds are laying out, as a plain table (in geometry); a theodolite, Gunter’s chain, and measuring laths; with any similar articles, as spare thermometers, budding-knives, &c.

1702. The seed-room may be connected with the office by a door in the lobby. This should be a small room, well ventilated, with a cabinet of drawers, as in a common seed-shop, but on a smaller scale, and somewhat different system. The lower tier of drawers should, of course, be the largest, and may be one foot deep by two wide on the face, and eighteen inches broad within. This tier will serve for beans, peas, acorns, mast, &c. A second may be three fourths the size, for carrot, turnip, spinach, larch-seed, &c. A third, half the size, for salad-seeds; and the fourth for those of pot and sweet herbs, need not be more than four inches deep on the face. The upper part of the cabinet may consist of shallow drawers, divided into ten or twelve compartments each, for flower-seeds; and on the top of all, as being least in requisition, similar shallow drawers, with moveable partitions for bulbous roots. As the kind or kinds placed in each drawer will probably vary every year, it seems better that their names should only be written on paper and pasted on. There ought to be a small counter, with a weighing machine (that of Medhurst is preferable); an ink-piece placed on it, and drawers, with paper bags, packthreads, &c. below. Some seeds, which it is desirable to keep in the fruit, as capsicum, pummion, &c. may be suspended from rows of hooks, fixed in the ceiling.

1703. The fruit-room may be connected with the seed-room. This ought to be well ventilated, for which purpose, like the three other rooms, it ought to have a small fireplace. The fruit-room was formerly a mere loft, where fruits were kept on the floor in common with onions, with no proper means of separation, or arrangement for systematic consumption. Now, however, they are regularly fitted up, either with shelves of lattice-work, on which to place sieves of different sorts of fruit; or with close shelves, for jars, boxes, &c. according to the various modes adopted of preserving them. The room may be of any form, but one long and narrow (fig. 282, a, a) is generally best adapted for ventilation and heating, or drying, when necessary, by a flue. The system of shelves (b, b) may be placed along one side, and may be raised to the height of six feet or more, (c, c) according to the number wanted. These shelves are formed of open work (d, d), on which to place square sieves of fruit, each of which should be numbered, and a table or slate (e), containing the corresponding numbers, may be hung up in the room, and
opposite each number should be a space for noting down daily the number taken out of each sieve for use. From this table statements may be made from time to time of the quantity of fruit on hand for the use of the house-steward. (Forsyth, in Hort. Trans. vol. ii. 76.) Forsyth directs that all the floors or shelves on which apples are to be kept or sweated, should be made of white deal, as when red deal is made use of for these purposes, it is liable to give a disagreeable resinous taste to the fruit, and spoil its flavor; when white deal cannot be procured, he advises covering the shelves with canvas. Those sorts of fruit which keep longest are generally best preserved in jars, excluded from the air, and placed in cold dry situations, not under 32° or above 40°.

1704. The root-cellar should be placed beneath the office and seed-shop; and the fruit-cellar below the fruit-room, and both descended to from the lobby. The great object is to keep the air in these apartments cool, and always, as near as possible, of the same degree of coolness: and for this purpose the windows should be small, placed below the ground level, and furnished with double or treble casements or sashes. These cellars should also be approached through double doors for the same reason. The fruit-cellar may be fitted up with bins or cells, like a wine cellar, in which casks and jars or sieves of fruit may be placed; and the root-cellar may have a few divisions on the ground to keep different roots apart, and sand, to keep them of uniform plumpness or moisture.

1705. The seed rooms or garrets may consist of one for drying and cleaning seeds; one for drying bulbous roots, as onions, hyacinths, &c.; and one for drying fruits or preserving them there. In all of these rooms, there should be hooks from the roof for hanging bundles of pot-herbs, branches of seeds, sieves, bags, &c. and a movable table or counter in the centre of each, with lattice-shelves below for holding sieves of roots, seeds, or fruits. A very small fanning-machine, and a couple of grooved cylinders to act as a threshing-machine, or a Meike's hand threshing-machine (fig. 283.) to be worked by two men, are requisite appendages of the seed-room. Supposing these rooms to form one wing to the gardener's house, the office opening into his kitchen; then the other wing may consist of a tool-house and men's living-room on the ground-floor; cellars for potatoes and fuel for their use under, and sleeping-apartments over, with a door, lobby, and stair, corresponding with the other wing.

1706. The tool-house is commonly a small apartment in the back sheds of hot-houses, in which the tools are laid down or piled up in the angles promiscuously; but in a proper tool-room, wherever situated, there should be contrivances of different sorts for hanging up the tools, so as their important parts, such as the teeth of rakes, blades of hoes, and spades, &c. may always be so exposed, that the master may see whether or not they are properly cleaned. There are certain tools, of which each workman appropriates one to himself, as spades, scythes, &c.; in these cases a small space should be allotted to each hired man, with his name affixed, &c. Watering-pots, syringes, engines, &c. should have their moveable parts separated, and be reversed, in order that they may drain and continue dry. Lists, nails, and mat-ties, should be kept in close drawers. Pruning-instruments oiled, and laid horizontally on latticed shelves or pins. A grindstone and other stones, and hones, with a vice, and files for sharpening the tines and teeth of forks and rakes, are the appropriate furniture of the tool-house.

1707. The lodge for under-gardeners should never consist of less than three apartments or divisions; first, an outer lobby, with a pump and exit for water, in which the workmen may wash their hands on entering to their meals, and the party who acts as cook or servant, which is generally taken by turns, may wash, scour, &c.; secondly, the cooking and living room, in which should be an economical kitchen-range, with an oven and boiler included, and proper closets, cupboards, tables, &c. to expedite and simplify cooking; and, thirdly, the bedroom over, where the bedsteads should be of iron, narrow, and without curtains, and for not more than one person. To each bed, there should be a small clothes-press, in which should be kept the linen, &c. belonging to each bed, and for which the occupier ought to be rendered responsible. A cellar for fuel and edible roots should be formed below. It is a common practice to place the lodges for working gardeners behind the hot-houses, or some high wall, in what is called a back shed. There, in one ill-ventilated apartment, with an earthen or brick floor, the whole routine of cooking, cleaning, eating, and sleeping is performed, and young men are rendered familiar with filth and vermin, and lay the foundation of future diseases, by breathing unwholesome air, and checking the animal functions by cold and damp. How
masters can expect any good service from men treated worse than horses, it is difficult to imagine; but the case is ten-fold worse, when head-gardeners and their families are compelled to lodge in these shed-houses. Independently of filthy and incommodiousness, the mother never fails to contract, early in life, rheumatism or ague; and it is only the extreme healthfulness of the employment of gardening, and the consequent vigor of the operatives, that ward off till a later day the same and similar diseases in the fathers and journeymen.

1708. As a general arrangement of a gardener’s house, office, and other appendages, the house may form a centre; the office, seed and fruit apartments, cellar, and garrets, one wing; and the lodge for under-gardeners, tool-house, &c. the other.

1709. A line of sheds is generally placed behind the range of hot-houses, or behind the hot-wall, or other high wall of the garden. These are used as stores, or places of reserve for utensils, machines and implements, and for working-sheds. The width and height of this line of sheds is necessarily regulated by the height of the wall. The roof of the shed being towards the north, and therefore without the advantage of the sun to dry it after rains, should not make an angle of less than 40° degrees with the horizon, and as the lower wall or line of props ought, at least, to be seven feet high above the level of the floor of the shed, the width is guided accordingly. All the fitting up requisite for the part destined to hold materials, is a few hooks and projecting pins for ladders, &c. and a sound floor, either paved or prepared with mortar, Roman cement, and scoria; and the whole, or the greater part of the division may have props or piers in front, instead of a wall and windows. As these sheds generally contain the hot-house furnaces, each of these, or every pair or group of them, ought to be enclosed with a low parapet to retain the fuel, give an orderly and neat appearance, and guard against accidents by fire, which might communicate with mats, litter, &c. Doors generally communicate with the hot-houses at different points, and near to each of these should be a bench or table on which to set or shift pots, &c.

1710. The part of these sheds more particularly set apart for working, ought to be enclosed with a wall on all sides, and warmed by a fire-place or flue. It ought to be perfectly light, and well aired by having numerous windows, and along these a range of benches or tables, for potting cuttings or bulbs, sowing seeds, preparing cuttings, number-tallies, painting and naming them, preparing props for plants, hooks for layers, lists for wall-trees, making baskets, wattled hurdles, and a great variety of other operations performed in winter, or severe weather, when little or nothing can be done in the open air. It may by some be thought too great a refinement to place a fire-place or a flue in such sheds; but if work is really expected to be done in them in cold weather, the saving will soon be rendered obvious.

1711. In small gardens, where there are no hot-houses, one small building is generally devoted to all the purposes for which the office, seed, tool, and fruit rooms, and working-sheds, are used. This should be fitted up with some degree of attention to the various uses for which it is designed, and a fire-place never omitted.

1712. Entrance lodges and gates more properly belong to architecture than gardening. But, as in small places, they are sometimes designed by the garden-architect, or landscape-gardener, a few remarks may be of use. In respect to style, the lodge ought always to bear as much analogy as possible to the mansion. If the one is Grecian, so should the other; but the lodge should display less decoration, because, as the mind naturally ascends from the less to the greater, the lodge would otherwise prove a false index to the mansion. In regard to general form, a cubic mass with a central chimney, is an unvaried comfortless-looking dwelling, especially when small. It is an attempt to form a whole without composing it of parts. A lodge, however small, to be a picturesque object, ought to contain a principal and subordinate mass or masses, and in the composition of which, the gate and piers may form one gradation. In respect to accommodations for the occupier, it ought never to contain less than three apartments—a kitchen or living-room, back kitchen, and sleeping-room, with the usual conveniences; and, at least, two sleeping-rooms where there are children. A handsome architectural entrance is but a poor compensation for its want of harmony with the mansion, of which that at Sion-House is an instance, and that at Blenheim of the contrary. But architects, like all of us, are sometimes so wrapt up in their art, or their favorite part of it, that they forget that congruity of parts is essential to the unity of the whole.

1713. Buildings for raising water. There are various contrivances for procuring water in garden-scenery, where it is not found in springs, rills, or lakes; and where it is found, of collecting and retaining it. The principal of these are wells, conduit-pipes or drains, and reservoirs.

Wells are vertical excavations in the earth; always of such a depth as to penetrate a porous stratum charged with water, and mostly as much deeper as to form a reservoir in this stratum or in that beneath it. A well otherwise excavated is a mere tank for the water which may ooze it from the surface strata. The form of the well is generally circular, and to prevent the crumbling down or falling in of the sides, this circle is lined with timber, masonry, or zones of metal. The earthy mi-
terials being thus pressed on equally in every point of this circle, are kept in equilibrium. When the well is not very deep, and in firm ground, this casing is built from the bottom to top, after the excavation is finished; but when the soil is loose, the excavation deep, or its diameter considerable, it is built on the top in zones, sometimes separated by horizontal sections of thin oak boards, which, with proper management, sink down as the excavation proceeds. There are various other modes, which those who follow this department of architecture are sufficiently conver- sistent with. The height to which the water rises in the well, depends on the height of the strata which supply the water; occasionally it rises to the surface, but generally not, within a considerable distance. In this case it is raised by buckets and levers (fig. 284.), by buckets and hand-machines placed over the well, or by buckets raised by horse-machines. (C. 283.)

1714. The lever and bucket mode is the most ancient and the simplest. It is common in the market-gardens round London and Paris, and in most of the villages from France to Berlin, Warsaw, Moscow, Astracan; and, we are told, it is to be seen in Turkey, Persia, India, and China. The hand and horse-machines are more recent inventions, applicable to market-gardens.

1715. The process of boring the earth for water has of late been successfully practised in various places, and especially at Tottenham, Middlesex, and Mitcham, Surrey. An augur like that used in draining is employed. The augur head is kept open by the hand, as the other as they are pushed down. Up these tubes the water rises to the height of the source of the spring, and when this height does not reach the surface, a well is dug down to the level to which the water will rise. It is evident that where the spring will rise to the surface boring must be a great saving, but less so in proportion as the source of the spring is low. (London Journal of Arts, &c. Oct. 1822. p. 304.)

1716. Pumps are of various kinds, as the lifting-pump; the forcing-pump, for very deep wells; the suction-pump; and the roller-pump, a recent invention for such as do not exceed thirty-three feet in depth. A good pump for gardens, where the water is not to be raised above twenty-eight or thirty feet in depth, is that of Robertson Buchanan (author of a Treatise on Heating by Steam, &c.), because this pump, which also acts by the pressure of the atmosphere, will raise drainings of dunghills, or even water thickened by mud, sand, or gravel. 1 The points in which it differs from the common pump, and by which it excels, are, that it discharges the water below the piston, and has its valves lying near each other. The advantages of this arrangement are—that the sand or other matter, which may be in the water, is discharged without injuring the barrel or the piston-leathers; so that besides avoiding unnecessary tear and wear, the power of the pump is preserved, and it is not apt to be diminished or destroyed in moments of danger, as is often the case with the common and chain pumps; that the valves are not confined to any particular dimensions, but may be made capable of discharging every thing that can rise in the suction-piece without danger of being choked; and that if, upon any occasion, there should happen to be an obstruction in the valves, they are both within the reach of a person’s hand, and may be cleared at once, without the disjunction of any part of the pump. It is a simple and durable pump, and may be made either of metal or wood, at a moderate expense. 2 Where clear water only is to be raised, Aust’s (of Hoxton) curvilinear pump is preferable even to Buchanann’s. The advantages depend on the curvilinear form of the barrel, which allows, and indeed obliges, the rod, the handle, and the lever, on which it works, to be all in one piece. Hence simplicity, cheapness, precision of action, more water discharged in proportion to the diameter of the barrel, and less frequent repairs. (REPORT OF ARTS, Jan. 1821.) Perkins’s square-barrelled pump is a practical improvement. (London Journal, &c.) but this and other contrivances for raising water will be found detailed in works on hydraulics.

1717. Conduits for watering gardens are either open or surface conduits, or internal tubes or apertures. Open conduits are not common in Britain, though very general in France and Italy. They are formed in the commonest gardens of peddled or well incorporated clay in the better part of brick, or rough stone lined with stucco or cement; and in the best, of hewn stone, in regular troughs, carefully jointed both by mechanical and chemical means. Internal tubes may be formed of timber, iron, lead, or earthenware. For mains or large supplies, cast-iron is the most durable, and timber the cheapest material; but for the minute ramifications necessary to afford supplies at different points, lead excels everything else. A beautiful application of the principles of chemistry to the joining of lead pipes, has been made by Kewley (inventor of the automaton gardener). Instead of a large gibbous joint, formed by plastering on a mass of solder at an expense both of material and time, which in inch-pipes amounts to at least Ss. a joint, Kewley prepares clear transverse sections on the extremities to be joined, places these in perfect contact, heats the pipe within a few degrees of the melting point, and then, with one drop of solder not larger than a pea, he forms a junction as perfect as if no separation had previously existed. By proper irons this is done in three minutes, at an expense, time and materials included, of not more than one penny per joint. Earthen pipes in a clayey sub-stratum may be used with economy, to convey water from one point to another; their disadvantages are liability to fracture or derangement from operations performed on the soil, to guard against which they should be laid not less than five to six feet in depth from the surface, and well bedded in worked clay. Conduits of common masonry can seldom be advantageously used on a small scale, unless for serving jointly as drains and conduits, but where they are eighteen inches or two feet in diameter, a complete cylinder of masonry may be formed, which, well executed, becomes very durable. It is observed, however, that all conduits of masonry, and even earthen pipes, can only be used
as such where the water is conducted along a level or declining bed; whereas by metal or wooden pipes, water may pass alternately over hollows and eminences, the latter not being higher than the source, without loss in the ground through which it passes.

1718. Reservoirs may be either tanks, cisterns, basins, or ponds. Tanks and cisterns are sometimes old barrels well tarred or painted, and then sunk in the soil; occasionally they are framed boxes of timber, the joints filled with oxide of lead and oil, and the whole pitched over, and then placed where they are to remain either above or on a level with the surface.

1719. Ponds or large basins (fig. 286.) are reservoirs formed in excavations, either in soils retentive of water, or rendered so by the use of clay. This clay is tempered, or made compact and tenacious, by working it so as to exclude the larger globules of air and water, and intimately unite all its parts with as much moisture as leaves it plastic. The bottom and sloping sides of the excavation, being smoothed and made firm, this tempered clay or puddle is to be spread evenly over it, from margin to margin, about a foot thick, and well compacted by beating. To preserve it from injury by the pressure of feet, or other accidents, it should be covered with gravel, in thickness according to the supposed liability to accidents. If cattle are to enter it, eighteen inches of coarse gravel, or stones covered with six inches of fine gravel, will not be too much. Sometimes these basins are lined with pavement, tiles, or even lead, and the last material is the best, where complete dryness is an object around the margin.

1720. Tanks or cisterns (fig. 287.) are generally excavations in the earth, lined with masonry, and sometimes raised two or three feet above it. This masonry is always built with mortar which sets or hardens under water, as the Dorking and other sorts of lime, gypsum, and any lime mixed with oxide of iron, in the form of what is called Roman cement, or Puzзолана earth. (Davy's Elements of Agr. Chem. lect. vii.) To protect this, the bottom of the cistern or basin is sometimes covered with six or eight inches of clay. Sometimes the bottom of the excavation for a pond or tank, is naturally a retentive clay, while the sides are of porous earth. In this case, the simplest way is to raise a wall, or vertical stratum of puddle (fig. 288.), from the horizontal stratum of clay, to within a few inches of the surface of the ground.

1721. Water for culinary purposes should be preserved in tanks, or in barrels interiorly charred, sunk deep in the ground, and rendered inaccessible to surface water. Tanks should be arched over with masonry, leaving, as ought always to be done in wells, a hole for the pump, sufficiently large to admit a man to clean or repair. A similar construction is proper for reservoirs of liquid manures, but they need not be so deep, as coolness in them is less sought for. (Butts's Agr. of Fland. 1812.) All reservoirs for pure water, to be used in gardening, ought to be exposed to the sun and air.

Sect. II. Anomalous Buildings.

1722. Collecting and preserving ice, rearing bees, &c. however unsuitable or discordant it may appear, it has long been the custom to delegate to the care of the gardener. In some cases also he has the care of the dove-house, fish-ponds, aviary, a menagerie of wild beasts, and places for snails, frogs, dormice, rabbits, &c. but we shall only consider the ice-house, apiary, and aviary, as legitimately belonging to gardening, leaving the others to the care of the gamekeeper, or to constitute a particular department in domestic or rural economy. That the subject of anomalous buildings may not occur again, we shall here conclude it by treating also of their management.

Subsect. 1. Of the Ice-house and its Management.

1723. The ice-house. Ice is kept on the continent in cellars, at a greater or less depth from the surface according to the climate. These cellars are without windows, surrounded by very thick walls, and entered by double and treble doors, sometimes placed in angular or circuitous passages, and always with intervals of several feet between them. Sometimes precautions are taken to carry off any water which may arise from a partial thaw, by forming gutters across the floor, and covering it with a grading of strong lattice-work, leading to a cess-pool in the passage, whence the water can be taken out by utensils without opening the inner door; but very frequently full confidence is had in the coolness of the situation, especially if the surrounding soil be dry. Where the surrounding soil is moist, a frame-work or cage of carpentry, grated at bottom, is constructed in the cellar, so as to be from one to two feet apart from the floor, sides, and roof, and in this the ice is as perfectly preserved as in a dry soil. (Cours, &c.; Bordley's Essays and Notes on Husbandry, Philadelphia, 1780.) Ice is kept in the cellars of con-
fectioners, and also by some of the market-gardeners, in heaps, with a very thick covering of straw or reeds.

1724. To keep ice in stacks or heaps in the open air, an elevated circular platform (fig. 289. a) is raised of earth; on this the ice is piled up in a conic form during a severe frost, and the addition of water enables the builder to form the cone very steep. On this cone wheat-straw is laid a foot in thickness (b), over this a stratum of faggot-wood or spray (c), and finally another thick stratum of thatch or long litter of any sort (d). In this way ice will keep a year, care being taken to expose it to the air as short time as possible in taking supplies.

1725. The form of ice-houses commonly adopted at country-seats, both in Britain and in France, is generally that of an inverted cone, or rather hen's egg, with the broad end uppermost. (fig. 290.)

1726. The proper situation for an ice-house is that of a dry spot of ground; as, wherever there is moisture, the ice will be liable to dissolve: of course, in all strong soils which retain the wet, too much care cannot be taken to make drains all round the house to carry off moisture. The situation should likewise be elevated, that there may be descent enough to convey off any wet that may arise near it, or from the ice melting; and also as much exposed to the sun and air as possible.

1727. The depth and diameter of the ice-well should be proportioned to the quantity of ice wanted; but it is always best to have sufficient room, as when the house is well built, it will keep the ice two or three years: and there will be this advantage in having it large enough to contain ice for two years' consumption, that if a mild winter should happen, when there is not ice to be had, there will be a stock in the house to supply the want. Where the quantity wanted is not great, a well of six feet diameter, and eight feet deep, will be large enough; but for a large consumption, it should not be less than nine or ten feet diameter, and as many deep.

1728. The excavation for the ice-well, where the situation is either of a dry, chalky, gravelly, or sandy kind, may be made entirely below the surface of the ground; but in strong loamy, clayey, or moist ground, it will be better to raise the well so high above the surface, as that there may be no danger from the wetness of the soil.

1729. In building the ice-well there should be a space about two feet deep left at the bottom (fig. 290. a), for receiving any moisture which may drain from the ice, and a small underground drain (b) containing a stop or trap for the exclusion of air (c) should be laid from this, to carry off the wet. Over the space at bottom (a) should be placed a strong grate of wood or a cart-wheel, to let the moisture fall down, which may at any time happen from the melting of the ice. The sides of the well (d) must be walled up with brick or stone at least two feet thick; or the wall may be built hollow. When the proper height is attained the wall may be arched over with two arches with a vacuity between, and leaving in the centre a hole for the admission of the ice (e), and in the sides a door for taking it out (f). This door, in order the better to exclude the air should open into a porch (g) with the three other doors, the spaces between which should be filled with straw to exclude more effectually the heat of the atmosphere. The whole being covered first with a layer of tempered clay and next with a hill of earth, the appearance will not be disagreeable (fig. 291.) and may be made ornamental.

1730. Management. When the house is finished, it should have time to dry before the ice is put into it; as when the walls are moist, the damp of them frequently dissolves the ice. At the bottom of the well, upon the wooden grate, some small faggots should be laid; and if upon these a layer of reeds be placed smooth for the ice to rest upon, it will be better than straw, which is commonly used. In the choice of the ice, the thinner it is, the better it may be broken to powder; as the smaller it is broken, the better it will unite
when put into the well. In putting it in, it should be rammed close, and a space left between it and the wall of the well, by straw being placed for the purpose, so as to give passage to any moisture that may be collected by the dissolving of the ice on the top or otherwise. If snow is used instead of ice, it ought to be pressed very firmly together, so as to exclude air, and in fact approach in texture to ice. To aid in consolidating both ice and snow, a little water may be occasionally poured over it from the rose of a watering-pot. In putting the ice into the house, some mix a little nitre or common salt with it, to make it congeal more fully; but this is not necessary. As the ice becomes solid in the well, an iron crow is necessary to take it up with.

1731. An ice-cold chamber is found of great use in horticulture, in preserving gathered vegetables, as peas, beans, cauliflowers, &c. in a fresh state, for some time after they are gathered. Potatoes and other tubers and bulbs, also plants in pots, cuttings, &c. may have their vegetation retarded by being placed in so cold an atmosphere. Several ice-houses, Neill informs us, excellently adapted not only for the main purpose, but for these secondary views, which nowise interfere with the other, have lately been constructed in the neighbourhood of Edinburgh, under the directions of Hay, particularly at Dalmeny Park and Dundas Castle. These ice-houses have double walls, a passage being left between the outer and inner. In the thick wall immediately enclosing the ice, are four recesses, with stone shelves for receiving the vegetables or fruits. In the outer wall, the same object is provided for. The roof, it may be added, is arched with stone, and has a hole in the top, over the centre of the ice-chamber, for introducing the ice. The passage between the two walls is likewise arched, and has two or three small grated apertures, which are closed with fitted stones, and may be opened for the purpose of admitting light and air when wanted. (Supp. to Encyc. Brit. art. Hort.)

1732. If an ice-cellar was added to the domestic offices of country-seats, and the ice preserved in it, and placed under the immediate care of the steward or housekeeper, it would certainly be more convenient for culinary use, and attended with less risk of melting when ice was taken out. Ice-cold rooms, which would be found useful for various purposes in domestic economy, might be formed adjoining. It is possible, however, that artificial modes of producing cold and ice as wanted, may supersede the use of ice-houses altogether. A very scientific view of the subject of ice-houses will be found in Rozier's Dict. of Agr., and in Nouveau Cours d'Agriculture, &c. art. Glacière.

SUBSEC. 2. Of the Apiary and the Management of Bees.

1733. The care of bees seems more naturally to belong to gardening than the keeping of ice; because their situation is naturally in the garden, and their produce is a vegetable salt. The garden-bee is found in a wild state in most parts of the globe, in swarms or governments; but never in groups of governments so near together as in a bee-house, which is an artificial and unnatural contrivance to save trouble, and injurious to the insect directly as the number placed together. Thus, if ten acres are sufficient to maintain two hives, a hundred acres will be required to maintain twenty; but while, in the former case, the hives being placed in the centre of the ten acres, each bee need not perform a longer journey than two hundred yards; in the latter, the colony being similarly situated as to the hundred acres, the average journey for each insect will be nearly a mile. Hence, independently of other considerations, one disadvantage of congregating hives in bee-houses or apiaries. The advantages are, greater facility in protecting from heats, colds, or thieves, and greater facilities of examining their condition and progress. Independently of their honey, bees are considered as useful in gardens, by aiding in the impregnation of flowers. For this purpose, a hive is sometimes placed in a cherry-house, and sometimes in peach-houses; or the position of the hive is in the front or end wall of such houses, so as the body of the hive may be half in the house and half in the wall, with two outlets for the bees, one into the house, and the other into the open air. By this arrangement, the bees can be admitted to the house and open air alternately, and excluded from either at pleasure.
1754. The apiary, or bee-house. The simplest form of a bee-house consists of a few shelves in a recess of a wall or other building (fig. 292) exposed to the south, and with or without shutters, to exclude the sun in summer, and, in part, the frost in winter. The scientific or experimental bee-house is a detached building of boards, differing from the former in having doors behind, which may be opened at any time during day to inspect the hives. In both kinds of houses, small holes, say half an inch high and three inches wide, with a small projection as a landing-place, are made in the front shutters, opposite the situation of each hive on the shelf. The upper part of these openings or entrances is sometimes guarded by a horizontal fillet to throw off the rain. Bee-houses may always be rendered agreeable, and often ornamental objects: they are particularly suitable for flower-gardens; and one may occur in a recess in a wood or copse, accompanied by a picturesque cottage and flower-garden. They enliven a kitchen-garden, and communicate particular impressions of industry and usefulness.

1755. The position of the apiary is thus treated by Huish: in the southern countries the aspect which is preferred is always to the eastward; in the northern countries, it is always to the eastward and the southward; but in England little or no attention is paid to the aspect. It is certain, however, that the aspect of the apiary should vary with the climate of the country; and in this climate, there can be little doubt that two points to the eastward of south, is the best.

Protection from high winds is essential in whatever position the hives are placed. In this country, therefore, a protection from the south-west is advisable. The high winds not only prevent the bees from leaving the hive in quest of honey, but they also surprise them in the fields, and often kill them by dashes them against the trees and rocks, or into the rivers.

A good position for an apiary should always be placed in a right line; but should the number of the hives be great, and the situation not capacious enough to admit of their being placed longitudinally, it is more advisable to place them over one another, on shelves, than in double rows on the ground. A bee, on leaving the hive, generally forms an angle of about forty-five degrees with the horizon of the hive should, therefore, be at a little above the elevation of the hive, and not two feet from the ground, in order to protect it from humidity. The greater the elevation of the hive, the longer is the flight of the swarm; and when they are at a certain point of elevation, the swarms are lost forever to the proprietor. If the hives are to be placed in a double row, the hider ones should alternate with, and be placed at, such a distance from the front ones, that when the bees take their flight, no obstruction is offered to their ascent.

Placing several hives upon the same bench, is very injurious, and during the swarming season, it is often attended with very destructive consequences. Huish was once requested by a gentleman to perform an experiment. A hive, which was placed on the same bench with six others, and in attempting to move the hive destined for the operation, the others were agitated, and the whole apiary became in a little time in a state of confusion. The easy access also, which the bees of one hive have to those of another, promotes quarrels and murderous battles. It is an erroneous opinion, though held by some skilful apiarists, that the addition of one apiary keeps the other, and that it is only the bees of a foreign apiary, with whom they quarrel. Huish having been often witness of the destructive animosity of these little insects, and the wars which they wage upon the weaker hives in their own establishment, endeavours to impress in the attention of every one, to place every hive upon a respective pedestal. In general a post is placed at each corner of the stand, as some prejudiced people believe that a hive stands firmer upon four feet than upon one; but Huish is certain that they who have once used the single pedestal, will never have recourse again to the four-legged stool. Another advantage particularly arises from the use of a single pedestal, which is, that the hive may be chained down and locked.

The apiary should be kept particularly clean; all noxious weeds carefully removed, and no rubbish left in which the enemies of the bees can conceal themselves. A few low trees or shrubs, planted in the vicinity of the apiary, will be found useful in arresting the flight of the swarms, for they very often alight on espeller trees, or on currant and gooseberry bushes. It is essential, however, to observe, that the apiary should not be incommodeed with herbs or plants, which rise to a height equal to, or exceeding the entrance of the hive; because the bees, on their arrival from their journeys, being much fatigued, are sometimes blamed in these plants, and therein their habitation with difficulty. If they touch these plants on passing, they often fall to the ground, and become victims to their enemies, or are unfortunately trodden under foot. Such plants also serve the purpose of a ladder, for the enemies of the bees to ascend into the hive, and especially the ants, which in some districts are particularly numerous. These little insects are a great diminution to a hive, and they require the most vigilant attention of the apiarist to prevent their depredations. I have found that a small leaden reservoir of water, encircling the bottom of the pedestal, is of great service in preventing the ascent of these insects.

The necessity of a good situation is not a proper situation for an apiary. The smoke of a city is very detriments to bees, and the chimneys are in general the resort of the swallows and martins, who are great destroyers of these insects.

The proximity of a large river is also injurious, as the bees in their homeward flight are often dashed into, or fall while flying from fatigue.

1756. The position of hives, according to Dr. Howison, should be such as to receive the rays of the rising as well as meridian sun; heat and light appearing the principal stimulants to the action of bees. A hive so situated as not to be troubled by the sun until some hours later than the other hives in the same garden, in the course of the season, lose a proportional number of days labor. Hives should stand at some distance from walls and hedges. When lately building a garden-wall, with a good exposure for bees, I ordered a number of niches to be made, into which 1 afterwards put hives. These were, however, too much infested with snails in summer, and mice in winter, that I was under the necessity of removing them to a more open situation.
1738. The Polish hive, or log-hive, (Patiska Pal.) (fig. 293.) may be considered as the primitive form of artificial dwellings for bees. It is simply the trunk of a tree, of a foot or fourteen inches in diameter, and about nine feet long. It is scooped out (boring in this country would be better) for about six feet from one end, and is cut at the bottom into a hollow cylinder of that length, and of six or seven inches in diameter. Part of the circumference of this cylinder is cut out during the greater part of its length, about four inches wide, and a slip of board is made to fit the opening. On the sides of this slip (a), notches are made every two or three inches across the face to allow a single bee to pass. This slip may be furnished with hinges and with a lock and key; but in Poland it is merely fastened in by a wedge. All that is wanting to complete the hive is a cover at the top to throw off the rain. This, it requires only to be placed upright like a strong post in the garden so as the bottom of the hollow cylinder may be not nearer the ground than two feet, and the opening slip look to the south. When a swarm is to be put in, the tree, with the door or slip opened, is placed obliquely over it; when these square frames are placed on the ground, and the hive standing with clay till the hive is planted or placed upright. When honey is wanted, the door is opened during the finest part of a warm day, when most of the bees are out; its entire state is seen from top to bottom, and the operator, with a lighted rag, to keep off the bees from his hands, cuts out, with a hooked knife, as much comb as he thinks fit. In this way fresh honey is obtained during the whole summer, the bees are never cramped for room, nor does it become necessary to add to them. The old comb, however, is annually cut out to prevent or lessen the tendency to swarming, which, notwithstanding this, and the size of their dwelling, they generally do once a year; for the laws of nature are not to be changed. Though it is a fact that a small swarm of bees will not do well in a tree, the hive extend in length and in breadth, it is admitted both by Huber and Huish, that they will thrive in it. "If too great a diameter," says Huber, "be not given to the abode of the bee, it may without danger be increased in the elevation, their success in that case is certain;" and the naturalist proves the truth of this assertion. We witnessed in 1813, near Grodno, the management by a woman, Panna Andrieuseshieniowna, (N. M. Magazine, June 1813.) in whose house we lodged, of above a dozen of these hives, for nearly four months, and are of opinion that her merit a trial in this country. It is singular, that this should be almost the only one continental hive that Huish, who seems to have paid more attention to the subject by foreign travel, study, and practice, than almost any man, has not seen. In Poland, he says, the inhabitants have no regular bee-hives. (Treatise on Bees, 3d edit. 1817, p. 32.)

1740. The glass hive is variously constructed, sometimes with two of the sides of glass in order to see the bees at work; at other times the hive is entirely of wood or straw, but with a flat surface at top, pierced with holes about an inch diameter, on which to insert crystal bell-glasses or drinking-glasses, in which the bees may be seen at work, and which glasses, when filled with honey, may be removed and replaced by empty ones, and thus occasional supplies of fresh honey obtained during summer. In the glass hive of White and Thorley, one large globe is used, which, as often as filled, is removed and replaced by an empty one. Such hives must necessarily be placed in the bee-house, or under a proper cover to exclude the weather. Huish says, "they are fit only for the amateur, or those persons who wish to have a little fine honey during the season, but who have no inclination to preserve the bees for the benefit of the succeeding year."

1741. The storying or pyramidal hive admits of increase, by the addition of horizontal sections of case, whether of straw or timber. The object is to produce a very strong hive; but the work carried beyond a certain point, is found injurious, rather than otherwise. (Huish, p. 67.)

1742. The hive of Palteau (fig. 294.) is composed of three or four frames, each a foot square, with three inches in height. These frames are placed the one on the other, and the first and last can always be lifted without deranging the work in the others. Each square is strengthened from every side by a cross piece of eight or ten inches in width, and two lines in thickness, which serves to sustain the comb of the bees. All the frames are tied together by means of these cross pieces; a board is placed on the top; and a green cloth is spread over the whole to guard it from the effects of the seasons. In autumn, when the honey is to be taken from this hive, the cross pieces are untied, and one or two of the upper frames are removed, passing the long blade of a knife or a wire between. This done, an empty frame is placed above, and another under all the rest, which make up for the two removed. "In an hour after," says Bose, who describes and recommends this hive, "the bees are at work as if nothing had happened; and the same operation can be renewed to infinity."

1743. Huish's hive (fig. 295.) is about the capacity of the common straw hive (1738.), in shape like a flower pot, with a convex cover or its narrow end, with five or six constructed interiorly that each comb (c) may be extracted by itself without deranging the rest; the combs being attached to slips of board (b) placed across the mouth or top of the hive. Any one of them may be lifted up, and to this the tapering construction of the interior is favorable. To prevent the bees from working below the level of pierced plates of tinned iron (fig. 296. a), and to prevent human thieves from carrying off the whole hive, it is chained and padlocked (fig. 296. b) to a strong post, which serves also as a fulcrum. The inventor of this hive has tried it, he says, during the whole of this year, and the following he states as the mode of using it, and the advantages attending its construction. "At any time and season when I require some honeycomb, or at the end of the season, when I deprive my bees of their superfluous store, I open the top, and take the side boards out, from which having cut the honeycomb, I replace them in the hive, and the operation is

---

293

294
facilitated by having some vacant boards ready to supply the place of the full ones. This operation is very easily and speedily performed; it has the advantage of not disturbing the middle combs, and I have often deprived these hives of their honey without the loss of a single bee, excepting those few who left their stings in various parts of my dress. — Two very considerable advantages arise from the use of this hive; in the first place, there is never any occasion to make an addition to the hive at the bottom, when the bees, by lying out in clusters, declare that they stand in need of room; for the operation of depriving them of a part of their combs from the top, will give them the room which they require, and which they will soon replenish with honey. In the common hive it is customary, in this predicament, to place, what is called in Scotland an eek, which consists of from four to six bands of the same diameter as the hive; but, on taking away this eek in the autumn, I have seen the most injurious consequences result to the hive. It is, in general, performed by cutting the combs with a wire between the hive and the eek, and then, whilst one person lifts up the hive another draws the eek away; the hive then rests on the stool. Few persons, however, consider that, as the combs are cut parallel with the bottom of the hive, they will all touch the stool on which it stands, and I have thus known a whole hive perish. The second advantage is, that the whole of the interior of the hive is open to your inspection, and you are thus enabled to examine the devastation of the moth, or to ascertain the presence of any other enemy." (Treatise on Bees, p. 83. 1744 Dr. Howison's hive (figs. 297 to 299) for obtaining the honey without killing the bees, "consists of two distinct hexagons (figs. 297, 258); one placed above the other. The under is formed of six panes of half-inch deal, each measuring ten inches in width and eight in depth, and covered with a thin board at top. This forms a box that will contain two pecks' measure of corn, and which he considers as sufficient for the largest swarm. This is intended for the breeding, as well as winter habitation of the bees. The upper is of the same dimensions and form as the under at bottom, but, in order to give it a conical shape, for the more conveniently fixing therein a coat of straw, the panes at top are only five inches wide, which is also covered by a piece of board. The upper box has a moulding (fig. 297. a) fixed to its under part, which projects about a quarter of an inch, and so exactly embraces the upper part of the lower box, as to join these two firmly together. In the deal which forms the top of the lower box, are cut four oval holes (fig. 298. a), each one inch wide and two inches long, through which the bees pass into the upper. This communication, when not wanted, is shut by a board which moves on a nail in its centre. The small pane of glass (fig. 287. b), in the top of the upper box, admits of seeing the progress the bees have made in it, without separating it from the lower one. This pane is covered to exclude light and cold or heat by a small shutter (c). When the swarm is first put into the lower box, the communication is shut with the upper, until the bees have completely filled it lower with combs. The communication is then to be opened, when the bees will ascend, and, if the season is favourable and the swarm numerous, they will fill it also, but not until they have completely stocked the lower. By removing the straw covering, and looking through the glass in the upper box, it may be seen what honey has been collected. Should a part or the whole of it be wanted, it will only be necessary carefully to separate the upper from the lower box, and shut the board of communication. The upper box is then to be removed to some distance, and the bees contained in it driven off, on which they will immediately join their companions in the lower. So soon as the honey is taken from the box, it can be replaced, and if early in the season, the communication opened for making more honey; but if late, it must be kept shut until the hive has swarmed next summer. Both the lower hexagon (fig. 258.) and the upper (fig. 299.) contain the usual cross horizontal sticks (a, a, a) for supporting the combs. If honeycomb early next season is preferred to a swarm, then the communication must be opened about the beginning of June. All the honey procured in this way is remarkable for its purity, none of the cells having been ever polluted by the hatching of young bees. The greatest advantages, however, from this method, are the early and large swarms; the consequence of not killing the bees." (Calcundian Memoirs, vol. ii. p. 153.)
1745. Management of bees. Being of opinion that the common straw or Scotch hive is the best for general purposes, we shall give Dr. Howison's mode of management as the simplest and most effectual for the common end in view. If the lives of the bees are to be saved, then some of the others may be tried; and the most suitable for this purpose, we think, is the Polish hive, and the next best that of Howison. The most ingenious, and the fittest for an amateur, is no doubt that of Huish. The latter author justly remarks, that "there is no certain method, nor will one be ever discovered, by which a great harvest of wax and honey, and great swarms, can be obtained at pleasure: these are chimere, which it is folly to pursue; because the former depends on the seasons being more or less favorable to the secretion of honey, on the countries where the bees inhabit being more or less wooded and covered with flowers, and the latter on the fecundity of the queen. Hence that annual difference between the harvest of honey and wax, and the largeness or smallness of the swarms which is found in all countries. To the same causes may be attributed the fact, that a mode of treatment, which has succeeded one year, will not succeed the next, although the circumstances be almost the same in appearance. It is these differences and variations which, for the period of fifty-five years, have given rise to hives of different forms and materials, which have only tended to instruct us, that bees can inhabit, work, and collect provisions in vessels of every form, from the excavated trunk of the tree, as it is used in Poland and the northern countries, to the expensive and useless glass hive, or to the hive of Du Hamel; and, where no hollow trunk of the tree can be found, in the holes of walls, in chimneys, and under the roofs."

1746. Choice of bees. To the common observer, all working bees, as to external appearance, are nearly the same; but to those who examine them with attention, the difference in size is very distinguishable; and they are in their vicious and gentle, indolent and active natures, essentially different. Of the stock which I had in 1810, it required 250 to weigh an ounce; but they were so vicious and lazy, that I changed it for the stock which is better disposed on this circumstance. From this it appears, that bees endeavour to fill with combs whatever hive they are put into, before they begin to gather honey. Owing to this, the hive is too large for its inhabitants, the time for collecting their winter store is spent in unprofitable labor: and towards the latter part of the season, the hives are more than usually empty, and the bees being long before the hive becomes so filled with young bees as to produce a necessity for emigration, from which the cause of the season is too far advanced for the young colonies to procure a winter stock. I should consider it as a good rule in all cases, that the swarm should fill two thirds of the hive. The hives used by me for my largest swarms, weighing from five to six pounds, will contain two pecks measure of corn, and will yield, in a good season, eight Scott pints of honey, and for smaller swarms in proportion. Hives with empty combs are highly valuable for second swarms, as the bees are thereby enabled much sooner to begin collecting honey.

1748. Feeding of bees. Near the sea little honey is collected after the first week in August; but in high situations, where the flowers are later and heath abounds, the bees labor with advantage until the middle of September. These are the proper periods, according to situation, for ascertaining if the hives improve in strength. In the drones the proportion marks this time with more precision. If a large hive does not weigh thirty pounds, it will be necessary to allow it half a pound of honey, or the same quantity of soft sugar, made into a syrup, for every pound that is deficient of this material in the other hives. This proportion should not be less than two pounds, and may be given for the bees to make the deposit in their empty cells before they are rendered torpid by the cold.

1749. Preparing sugar for bees. I must here notice, that sugar simply dissolved in water (which is a common practice), and sugar boiled with water into a syrup, form compounds very differently suited for the winter store of bees. When the former is wanted for their immediate nourishment, as in spring, it will answer equally as a syrup; but if to be laid up as a store, the heat of the hive quickly evaporating the water, leaves the sugar in dry crystals, not to be acted upon by the trunks of the bees. I have known several instances of bees killed by hunger, while some pounds' weight of sugar in this state remaining in their cells. The boiling of sugar into syrup forms a closer combination with the water, by which it is prevented from flying off, and a consistence resembling that of honey, retained. I have had frequent experience of hives not containing a pound of honey, preserved in perfect health through the winter, with sugar so prepared; but if the proportion be not given quantity.

1750. Covering the hives. Bees are evidently natives of a warm climate, a high temperature being absolutely necessary to their existence; and their continuing to live in hollow trees during the severe winters of Russia and America, must depend on the heat produced from the great size of the swarms which inhabit those quarters. The hives are best covered when, always proper most the following summer. In consequence, about the end of harvest, I add to the thin covering of straw put on the hives at the time of swelling a thick coat, and shut up the aperture through which the bees entered, so that only one window at a time. Indeed, as a very small portion of air is necessary for bees in their torpid state, it were better, during severe frosts, to be entirely shut up, as numbers of them are often lost from being enticed to quit the hive by the sunshine of a winter day. It will, however, be proper at times to remove, by a crooked wire or similar instrument, the dead bees and other filth which may obstruct the performance of this season's increase.

1751. Treatment during the breeding season. To hives, whose stock of honey was sufficient for their maintenance, or those to which a proper quantity of sugar had been given for that purpose, no further attention was required, until the brood began to appear about the beginning of May, and in cold, about a month after. Owners of hives are often astonished, that at this advanced season, when their bees had, for weeks preceding, put on the most promising appearance, after a few days of rain, they become so weak and sickly as to be unable to leave the hive, and continue it. Let it be paid attention to at this season, a paying attention to the honey thieves, and the cause is as follows: The young bees for a short time previous to their leaving their cells, and some time after, require being fed with the same regularity that young birds are by their parents; and if the store in the hive be exhausted, and the weather such as not to admit of the working bees going abroad to collect food in sufficient quantity for themselves and their brood, the powerful principle of affection for their
young compels them to part with what is not enough for their support, at the expense of their own lives. To prevent such accidents, I make it a rule, that if, during the breeding season, it rain for two successive days, I would be very cautious to avoid any further hives, as it would be difficult to prevent their being molested by the cropped bees. The swarming season appears to be concluded when all the swarms have been accounted for.

1752. Swarming. For several years past, my hives have uniformly sent forth their first swarms during the second week in July, from which it appears, that early or late swarming, in the same situations, is not so much regulated by good or bad seasons as might have been expected. Near the sea this will, of course, take place some weeks earlier.

1753. Signs of swarming. The first swarming is preceded by the appearance of drones, and hanging out of working bees. The signs of the second are more equivocal, the most certain being that of the queen, which remains the last in the hive, and seems to be the last to make a flight. A sound resembling that of a cricket. It frequently happens that the swarm will leave the old hive, and return again several times, which is always owing to the queen not having accompanied them, or from having dropped on the ground, being too young to fly to a distance. In such cases, I have seen her found near to the old hive, and on being taken up, return immediately to the new one, from which she was removed a moment before.

1754. Late swarms. When a hive yields more than two swarms, these should uniformly be joined to others that are weak, as from the lateness of the season, and deficiency in number, they will otherwise perish. This junction is easily formed, by inverting at night the hive in which they are, and placing over it the one intended to receive them. They soon ascend, and apparently with no opposition from the former possessors, as I have never observed fighting to be a consequence. It being very universally believed that two queens cannot live together in the same hive, I have, for several days after this forced junction, searched for the ground, without ever finding any such, but never found the queen of the hive, after swarming, to be unfavorable for the bees going out, they must be fed with care until it clears up, otherwise the young swarm will run a great risk of dying. (Houldson, in Mem. Calc. Hort. Soc.)

1755. Taking the honey. This may be effected, even with hives of the common construction, by three modes, partial deprivation, total deprivation, and suffocation.

1756. Partial deprivation is performed about the beginning of September. Having ascertained the weight of the hive, and consequently the quantity of honeycomb which is to be extracted, begin the operation as soon as evening sets in, by reverting the full hive, and placing an empty one over it; particular care is to be taken that the same diameter of hive does not be reversed, or if they differ in the two, it will not be possible to effect the driving of the bees. The bees being placed on each other, a sheet or large cloth must be tied round them at their point of junction, in order to prevent the bees from molesting the operator. This is an arranged, beatiful, however, but particular caution must be used to beat on those parts to which the combs are attached, and which will be parallel with the entrance of the hive. The ascent of the bees into the upper hive will be known by a loud humming noise, indicative of the pleasure in finding an asylum from their enemy; in a few minutes the ascension is completed, and the bees have left the bottom of the hive, and are going upon the pedestal from which the full hive was removed. The hive, from which the bees have been driven, must then be taken into the house, and the operation of cutting out the honeycomb commences. Having extracted the requisite quantity of comb, this opportunity must be embraced of inspecting the hive, and cleaning it from any noxious matter. In cutting the combs, however, particular attention should be paid not to cut into two or three combs at once, but having commenced the cutting of one, to pursue it to the top of the hive; and this caution is necessary for two reasons. If you begin the cutting of two or three combs at one time, you will exhaust the whole of the honey, or perhaps take too much; if you stop in the middle of a comb, would be attended with very pernicious consequences, as the honey would drop from the cells which have been cut in two, and then the bees on being returned to their native hive, might be drowned in their own sweets. The bees, also, in their return to their natural domicile, being still under the impression of fear, would not give so much attention to the honey which flows from the divided cells; and as it would fall on the board, and from that on the ground, the bees belonging to the other hives would immediately scent the wasted treasure, and a general attack upon the deprived hive might be dreaded. The deprivation of the honeycomb being effected, the hive may be returned to its former position, and reversing the hive which contains the bees, and placing the deprived hive over it, they may be left in that situation till the morning, when the bees will be found to have taken possession of their native hive, and if the season proves fine may replenish what they have lost. (Huish’s Treatise on Bees)

1757. Total deprivation is effected in the same manner, but earlier in the season, immediately after the first swarm, and the bees, instead of being returned to a remnant of honey in their old hive, remain in the new empty one, which they will sometimes, though rarely, fill with comb. By this mode, it is to be observed, very little honey is obtained, the bees in June and July being occupied chiefly in breeding, and one, if not two, swarms are lost.

1758. Suffocation is performed when the season of flowers begins to decline, and generally in October. The smoke of paper, or linen rag soaked or smeared with melted sulphur, is introduced to the hive by placing two or three of these bags under the bottom of the comb, or the full hive may be placed on an empty one, inverted as in partial deprivation, and the sulphurous smoke introduced by fumigating bellows, &c. The bees will fall from the upper to the lower hive in a few minutes, when they may be removed and buried, and the combination of the hives reversed. Such a process seems one of the easiest, both to the insects themselves, and to human feelings. Indeed, the mere deprivation of life to animals not endowed with sentiment or reflection, is reduced to the precise pain of the moment without reference to the past or the future; and as each pulsation of this pain increases in effect on the animal mind, so on the other the susceptibility of feeling it diminishes. Civilised man is the only animal to whom death has terrors.

1759. Estimate of the humanity of the three modes. Much has been said about the cruelty of killing bees; but if man is entitled to deprive them either totally or partially of their food, he has an equal right (and in truth by that very act exercising it) of depriving them of their lives. For of the hives that have been partially or wholly deprived of their honey, it may be safely affirmed, that there is not one in ten that does any good. If they live till the succeeding spring they are commonly too weak to collect food or to breed, and, being plundered by their neighbours, dwindle away, till at last the hive is without inhabitants. A prompt death is surely preferable to one so protracted. — Some judicious observations on this subject will be found in Huish’s book, extracted from the works of La Grenée, a French apiarian.

SUBSEC. 3. Of the Aviary, and of Menageries, Piscinaries, &c.

1760. The aviary was common to the country-houses of the Romans, but used principally, as it would appear from Pliny, for birds destined to be eaten. Singing-birds, however, were kept by the Persians, Greeks, and also the Romans in wicker-cages; and these utensils, no doubt, gave rise to the large and fixed cage called an aviary; but in what
country, and in what age, appears uncertain. They are highly prized in China, and seem there to confer about a similar degree of dignity to a house and family as does a large conservatory in this country; for in the altercations which took place during Lord Amherst's embassy, it was stated, on the part of the emperor, that Sir George Staunton had profited greatly from China, and had built himself a house and an aviary. That they were in use in England in Evelyn's time, is evident from a memorandum entered in his diary, that the Marquis of Argyle took the parrots in his aviary at Sayes' Court for owls.

1761. The canary or singing-bird aviary used not unfrequently to be formed in the opaque-roofed green-house or conservatory, by enclosing one or both ends with a partition of wire; and furnishing them with dead or living trees, or spray and branches suspended from the roof for the birds to perch on. Such are chiefly used for the canary, bullfinch, linnet, &c.

1762. The parrot aviary is generally a building formed on purpose, with a glass roof, front, and ends; with shades and curtains to protect it from the sun and frost, and a flue for winter heating. In these, artificial or dead trees with glazed foliage are fixed in the floor, and sometimes cages hung on them; and at other times the birds allowed to fly loose. An aviary of this sort was built at Morden by the late Abraham Goldschmidt.

1763. The verdant aviary is that in which, in addition to houses for the different sorts of birds, a net or wire curtain is thrown over the tops of trees, and supported by light posts or hollow rods, so as to enclose a few poles, or even acres of ground, and water in various forms. In this the birds in fine weather sing on the trees, the aquatic birds sail on the water, or the gold-pheasants stroll over the lawn, and in severe seasons they be take themselves to their respective houses or cages. Such an enclosed space will of course contain evergreen, as well as deciduous trees, rocks, reeds, aquatics, long grass for larks and partridges, spruce firs for pheasants, furze-bushes for linnetts, &c. An aviary, somewhat in this way, was formed by Catherine of Russia, in the Hermitage Palace; and at Knowsley in Lancashire. In short these are the only sorts admissible in elegant gardens; since nothing surely to one who is not an enthusiast in this branch of natural history, can be more disagreeable than an apartment filled with the dirt and discordant music of innumerable birds, such, for example, as the large aviary at Kew. Birds from the hot climates are sometimes kept in hot-houses among their native plants, as in the large conservatories at Vienna. (218.) In this case, the doors and openings for giving air must be covered with wire cloth, and the number must not be great, otherwise they will too much disfigure the plants with their excrement.

1764. Gallinaceous aviary. At Chiswick, portable netted enclosures, from ten to twenty feet square, are distributed over a part of the lawn, and display a curious collection of domestic fowls. In each enclosure is a small wooden box or house for sheltering the animals during night, or in severe weather, and for breeding. Each cage or enclosure is contrived to contain one or more trees or shrubs; and water and food are supplied in small basins and appropriate vessels. Curious varieties of aquatic fowls might be placed on floating aviaries on a lake or pond.

1765. Wire-cages. In a flower-garden or pleasure-ground where the object is the singing of birds, much the most effectual mode is to distribute over it a number of common-sized cages containing different sorts of birds. They may either be hung on trees or fixed to iron rods. (fig. 300.) The more hardly sorts of British birds may remain there during night, and the more delicate sorts and canaries taken in either by removing the cage only or the cage and rod together (fig. 301.), and placing or fixing it in a shed or conservatory.

1766. Menageries were formerly attached to most of the royal gardens and parks of Europe. The most complete example is that of the Paris garden, constructed and arranged, as much as possible, according to the natures and habits of the different animals enclosed. The subject, however, can hardly be considered within our department.

1767. The piscinaria, cochlearium, ranarium, columbarium, &c. belong to that part of rural economy which forms the connecting link between rural and domestic economy.
Sect. III. Decorative Buildings.

1768. The general characteristic of decorative buildings is, that they are introduced more for their picturesque effect as parts of external scenery, than as absolutely necessary. Their construction, like the others, belongs chiefly to civil architecture and sculpture; but the choice and emplacement to gardening. Their variety is almost endless; but we shall rank a few selections under the different heads of useful, convenient, and characteristic decorations.

Subsect. 1. Useful Decorative Buildings.

1769. Useful decorations are such as while they serve as ornaments, or to heighten the effect of a scene, are also applied to some real use, as in the case of cottages and bridges. They are the class of decorative buildings most general and least liable to objection.

Subsect. II. Decorative Buildings.

1770. Cottages are of various sorts; one grand division is founded on the style of architecture employed, as Grecian, Gothic, Chinese, &c.; another, on the materials used, as stone, brick, timber, trees unbarked (fig. 302.), wicker-work, with moss or mud; and another, on the peculiar style of different countries, as English, Swedish, Italian, &c. (See Prin. of Design in Arch. 8vo. 1821.)

1771. The Gothic cottage is characterised by the forms of the Gothic or pointed style of architecture in the openings, as doors, windows, &c. in the chimney-tops and gable-ends. It may be thatched; but the most appropriate roof is grey slate, or slate stone, or flat grey tiles.

1772. The Grecian cottage is that in which the lines of Grecian architecture prevail. These are generally horizontal, and may be displayed in the windows, roof, and other parts. The roof is generally flat and projecting, and the best slate or flag stone seems the most approved covering.

1773. The Chinese cottage (fig. 303.) is characterised by concave lines in the roof, projecting eaves, small windows, and bell or drop ornaments. The proper roofing is parti-colored tiles, with which the walls may also be covered.

1774. The Bengal cottage has walls of mud, the openings surrounded by frames of bamboo, the doors and divisions of the windows of the same material, and the roof covered with reeds or palm-leaves.

1775. The English cottage is generally Gothic as to style, the lowest order formed of mud and thatched, with boarded labels over the windows and doors; the second order of
framed timber, filled up with brick-work, with oaken door and window-frames; and the third order of solid brick, with stone door and window-frames, and Gothic mouldings and labels. There is a very pleasing assemblage of picturesque cottages, mostly thatched, erected on the grounds at Blaze Castle, near Bristol. They are not only varied in form, for which much facility is obtained, by including two, and sometimes three dwellings, in one pile; but their disposition on the ground, and the surface of the ground itself, is varied; and by the management of the walks and trees, an eyeful of any part seldom contains more than two or three groups; always one in the fore-ground, and the others in the middle or remote distance. They were designed by Nash.

1776. The Scotch cottage is, as to architectural style, something between Gothic and Grecian. It is the same with the cottage of France and Flanders, is characterised by high narrow gable-ends, with notched or step-like finishings. The material of the walls, almost always stone; and of the roof, pantiles or grey schistus slate.

1777. The Italian cottage is characterised by Grecian lines, and forms bold projections and recesses, as far as a cottage admits of these; high pantiled roofs of a peculiar construction; the walls white-washed, and in farmers' cottages, especially in Tuscany, often a part of the roof raised as a sort of watchtower.

1778. The Polish cottage (fig. 304.) is formed chiefly of timber, with some plaster and wicker-work to thicken the walls within. The roof is covered with shingles or fir-timber split into pieces of about eighteen inches long, six inches broad, and half an inch thick. The ends are generally upright, not en pavillon, and the roofs projecting.

1779. The Russian cottage is also built of timber, but of solid logs or trees notched, and let into each other at the angles of the buildings where they intersect. They are roofed as in the Polish cottage, and sometimes highly ornamented at the ends by carved imitations of the sun, moon, stars, &c. protruded from the ends, and protected by the projection of the roof.

1780. The Swedish and Danish cottage is built of logs and moss, like the Russian.

1781. The primitive hut, or cabin, varies as to material, according to the country in which it is formed. The rudest description of artificial shelter for man is perhaps that used by the aboriginal inhabitants of Botany Bay, which is a large plate of the bark of a tree bent in the middle, and its two ends stuck in the earth. The African cottage (fig. 305.) is a low oblong mud hut, constructed by the natives as swallows do their nests. (Sir W. Ouseley.) The rudest European hut is generally a cone formed by branches, poles, or young trees, with their ends set in the ground, made to lean against each other at the top, such as are now in use in Lapland. (fig. 306.) They are then covered with spray, heath, straw, reeds, or turf. One opening serves the purpose of all others. In countries abounding in noxious reptiles, this is made in the upper part of the roof, and entered by a trap-door, as in Stedman's hut at Surinam, or by a ladder as in the huts of Morocco (fig. 311.); but in Europe the entrance is generally made on a level with the floor, as in the huts of
Ireland, the Highlands of Scotland, and Lapland. Modifications of this and other rude forms (figs. 307. to 310.) may sometimes be admitted in garden-scenery, as tool-houses, or shelters for other materials, game, &c. — A variety of examples of rustic huts and cottages are to be found in Kraft's plans, &c.; and of highly decorated cottages and ornamented buildings in Mrs. Hofland's White Knights, and Ackermann's Repository of the Arts.

1782. The bridge is one of the grandest decorations of garden-scenery, where really useful. None require so little architectural elaboration, because every mind recognises the object in view, and most minds are pleased with the means employed to attain that object in proportion to their simplicity. There are an immense variety of bridges, which may be classed according to the mechanical principles of their structure; the style of architecture, or the materials used.

With respect to the principles of their mechanical structure, the materials of bridges are held together, either by their gravity, as in all arches, whether of stone, iron, or timber; or by their tenacity, as in single planks, flat bridges of iron or timber, and those new and wonderful exertions of ingenuity, suspended bridges, of which fine examples have been executed across the Menai and the Tweed, and the principles of which we have elsewhere (Annals of Philosophy, Jan. 1816.) entered into at large.

With respect to styles of architecture, the bridge affords little opportunity of detailed display; but the openings may be circular or pointed arches, or right-lined, or a mixture of these.

As to material, bridges of tenacity are formed of timber or wrought-iron; bridges of gravity, generally of cast-iron or stone; but they may be formed of any material. We submit a few examples in different styles, and composed of different materials.

1783. The fallen tree is the original form, and may sometimes be admitted in garden-scenery, with such additions as will render it safe, and somewhat commodious.

1784. The foot-plank is the next form, and may or may not be supported in the middle, or at different distances by posts.

1785. The Swiss bridge (figs. 312, 313.) is a rude composition of trees unbarked, and not hewn or polished.

1786. The tied plank (fig. 314.) is formed by fixing the ends of one or more planks in two heads or cases of cast-iron (a, a), and then connecting them by wrought-iron rods (b, b) fixed to the heads in the manner of a string to a bow. A very light bridge is thus formed, which acts both by tenacity and gravity. Thus, when a light weight is on the bridge, the particles of the boards are not moved, but merely pressed on, and therefore the arched part may then be said to act by gravity; while this pressure being propagated to the abutments, these are held in equilibrium by the iron rods acting by their tenacity. On the other hand, when a bridge of this sort is heavily loaded, the
arch will bend down, or yield in some places and rise in others; in which case the whole acts by its tenacity.

1787. A very light and strong bridge may be formed by screwing together thin boards in the form of a segment, or by screwing together a system of triangles of timber. This principle may be carried to a great extent; by using so many lamina the elasticity of the materials is lessened without rupturing their parts, and though from the form of such arches, they would appear to act by gravity, yet in truth, they act more by tenacity, for the ends of the segment cannot be pressed out without rupturing the soffit, or crushing the crown of the arch. For broad tame rivers in flat grounds, such arches may be considered appropriate, as attaining the end without any appearance of great effort. (Fulton on Bridges; Howard on Military Bridges.)

1788. Bridges of common carpentry (figs. 315, 316.) admit of every variety of form, and either of rustic workmanship or with unpolished materials, or of polished timber alone, or of dressed timber and abutments of masonry.

1789. Bridges of masonry (fig. 317.) may either have raised or flat roads; but in all cases those are the most beautiful (because most consistent with utility) in which the road on the arch rises as little above the level of the road on the shores as possible; notwithstanding the prejudices of some eminent engineers (Telford, in Ed. Encyc. art. Bridge) in favor of the old practice of always forming the extrados of a considerable curve. It is only where masted vessels are to pass under, that the raising the arches higher than what is necessary for the transit of the stream can be considered in good taste.

1790. Cast-iron bridges are necessarily curved; but that curvature, and the lines which enter into the architecture of their rails, may be varied according to taste or local indications.

1791. The boat, as to construction, belongs to naval architecture. In gardening, it is sometimes used as a substitute for the bridge, sometimes worked by a mechanical power, as the wheel and pinion, and commonly with the deck arranged as part of the gravel walk, which approaches the edge of the water. But where a river with a current is to be crossed, the flying boat, with the deck arranged as part of the walk (fig. 318),
The motion of this boat is derived from the obliquity of its sides to the direction of the current, which must be kept up by the use of the rudder. The boat (a) must be anchored to a post (b) fixed in the middle of the river; and the longer the cable (c), the manoeuvre will be the more easily executed, provided the movement is not made in a greater arc than 90°. The force of the stream is at a maximum, when the angle formed by it, and the side of the boat is 54° 44'. The same purpose may be effected by a triangular raft without the use of a rudder. (Howard on Military Bridges, sect. 4. p. 97.)

1792. Sepulchral structures have been adopted as parts of garden-scenery from the earliest times. They are most common in the Protestant countries of Europe, and in England are to be found in parks and pleasure-grounds in various characters and styles, from the consecrated flower-plot, as at Nuneham Courtenay, to the superb mausoleum of Castle Howard, or of Cobham Hall.

The most ancient form of sepulchres seems to have been tumuli, barrows, or mounds of earth; sometimes planted, but generally left to acquire a clothing of turf. In cool regions, these may be considered the most durable of all tombs, because the turf and clothing of the turf prevent the earth from being washed or blown away by the weather, and the material presents no temptation to the avarice of mankind. Of such tombs there are several on a small scale in Wiltshire, and on a large scale round the city of Cracow; the last considered as the sepulchres of the ancient kings of Poland. The caire, or cap of rough stones, is the next form, common in some parts of Britain. To this succeeded the pyramid of Egypt. These are, in their nature and construction, calculated to serve as durable monuments, and were very properly employed by kings and chiefs in rude ages; for them, as now, the idea of being quite forgotten was far from pleasant. But in more modern times, these parts of men's actions, which are worth remembering, can be recorded in books, which, when good, are the most durable of all monuments. Such piles as have been mentioned are felt as too expensive, and considered as too gross a display of the love of fame; men, therefore, have recourse to what may be called emblems of monuments, known under the names of mausoleums, obelisks, pillars, tombs, vaults, stone coffins, sarcophagi, urns, &c.; all of which exist from general consent, and not from the indestructive nature of their materials or construction, as in the former class. The most unnatural form of sepulture, and the most liable ultimately to defeat the very end in view—respect to the memory of the deceased—is that in which the body is embalmed, richly dressed, and hermatically sealed up in a box or chest of durable materials, such as lead, and placed in a richly ornamented building of valuable stone. Here, in times of intestine war and rapine, the building will be broken into, and the lead and valuable materials taken from the body; but the stuff in which the body is wrapped may be an object, as was the case with the retrieving French army at Kowno and other places in 1812; or the architectural ornaments, and the dead bodies themselves, may be objects of research, as in the case of certain Grecian marbles taken by Lord Elgin, and the despoliation of numerous Egyptian tombs by Signor Belzoni and others. A very natural form of sepulture for a family residing on their own estate in the country, is a consecrated grove or enclosure, in which each individual is buried near a tree, inscribed with his name on the bark. All that an enemy or a new purchaser can do, is to cut down the trees, and change the state of the ground from pasture to arable. If the family have effected any great public good, it will be elsewhere permanently recorded; if they have not, it is fitting their names should, as indeed they always will, perish with their bodies. The utility of epitaphs and tombs in public groves or churchyards, however, it is not meant to deny; nor to impugn the different tastes of individuals. The grand object appears to us is to be the attainment of the greatest possible quantity of enjoyment, mental and corporeal, while living.

1783. As to monuments for the inferior animals, such as are to be found at Potsdam, Outlands, and Bramley Hall, we say, with that enviable and remarkable character the Prince de Ligne,

Lah ces vais monuments d'un chien ou d'un oiseau,
C'est profiter le doigt, insulter au tombeau.
or of roofs, consists in the judicious composition of ties and struts; the former always resisting a drawing or twisting power, and the latter one of a pressing or crushing nature.

1795. *By the maintenance of a gate's position,* we mean the resistance to that tendency which most gates have to sink at the head or falling-post, and thus no longer to open and shut freely. If the construction and hanging of the gate were perfect, this could not possibly take place; but as the least degree of laxity in trussing the gate, or want of firmness in fixing the post in the ground, will occasion, after frequent use, a sensible depression at the head, it becomes requisite either to guard against it as much as possible, in the first construction; or, to have, as in N. Parker's gate, a provision in the design of the upper hinge, for rectifying the deviations as they take place. In order to understand the construction best calculated to resist depression, suppose a gate hung, and resting on its heel (fig. 322. c), acting as a strut, and maintained there by its upper hinge (a), acting as a tie, then the bottom rail of the gate considered as representing the whole, becomes a lever of the second kind, in which the prop is at one end (c), the power at the other (g), and the weight placed between them in the line of the centre of gravity of the gate (l). Now, as two equal forces, to hold each other in equilibrium, must act in the same line of direction, it follows, that the power acting at the end of the lever (g), will have most influence when exerted at right angles to it or parallel to the line of gravity (g e); but as this cannot be accomplished in a gate where the power must be applied obliquely, it follows, that a larger power becomes requisite; but that the less the obliquity, the less will be the power, or in other words the less the strain on the construction of the gate, or the less the tendency to sink at the head. The half of the right angle (g e c), seems a reasonable limit, by which, if the power requisite to hold the weight in equilibrium, when acting at a right angle, be as the side of a square of the length of the lower bar of the gate (g c), then the power requisite to effect the same end, when acting at an angle of 45 degrees, is as the diagonal to this square (g h). By changing the angle to a parallelogram, the relative proportions will still be the same, and the advantages and disadvantages will be rendered more obvious. (For g d is not to d c, as g h is to h c.) It is evident from this principle, that gates whose upper line is concave, or falls from the posts or piers to the centre (fig. 320.), are more fitting, and consequently more beautiful, than such as are of an opposite description (fig. 321.) But a person totally ignorant of mechanical principles, but of good taste in visual matters in general, might prefer the latter, which shows, that a just or true taste must be founded on science or reason, and is by no means so vague and indefinite, or arbitrary an exertion of judgment as many are apt to imagine.

1796. *Compensation-hinges.* Where there is no choice between a construction calculated to resist sinking, and the common form, then the corrective or compensation-hinge of N. Parker (fig. 323.) is very proper for division-gates in parks or drives; but a scientific construction, either polished or rustic (fig. 326.), may be easily contrived for gates in forests and farms. When Parker's hinge is used, all that is necessary, when the gate sinks at the head, is to screw it up by the nut (a, fig. 323.) till it is replaced in its original position.

1797. *With respect to facilitating the motion of gates,* that is to be done by lessening the friction of their hinges. Friction is as the extent of rubbing surface, and the weight; therefore, of the two hinges of a gate, the friction of the heel, when a pivot, is by much the least, as the rubbing there is limited to one point, instead of the whole surfaces of two cylinders. Whatever, therefore, has a tendency to throw the preponderance of weight on the heel, must lessen the friction of the upper hinge. This will be accomplished in
proportion as the centre of gravity is moved from the centre of the gate towards the heel: and this, as well as additional strength, may be obtained by increasing the dimensions of the materials gradually from the head to the heel. — Some have proposed to suspend gates by weights, in the manner of windows, instead of hanging them, but excepting in anomalous cases, this would be an unsightly and inconvenient practice. (Farmer’s Mag. 1819.)

1798. The forces and directions of the strains on the hinges of gates has been practically explained and mathematically demonstrated by Bailey (Agric. Rep. Northumb.) and N. Parker. (Essay on Gates, 1816.) The turnpike-gate of the last author seems to be a very near approach to perfection.

1799. Substitutes for gates, such as the gate with falling bars (figs. 324, 325.) the stile, which is of various sorts; turn-wicket; horizontal grating; and various other modes of permitting man to pass a barrier and yet excluding cattle, belong rather to agriculture than to gardening.

1800. Gates, as decorations, may be classed according to the prevailing lines, and the materials used. Horizontal, perpendicular, diagonal, and curved lines, comprehend all gates, whether of iron or of timber, and each of these may be distinguished more or less by ornamental parts, which may either be taken from any of the known styles of architecture, or from heraldry or fancy.

1801. The published designs for gates are numerous, especially those for iron gates; for executing which, the improvements made in casting that metal in moulds afford great facilities. By a judicious junction of cast and wrought iron, the ancient mode of enriching gates with flowers and other carved-like ornaments might be happily re-introduced.

1802. Gates in garden-scenery, where architectural elegance is not required to support character, simple or rustic structures (fig. 326.), wickets, turn-stitles, and even move-
able or suspended rails, like the German schlagbaum (fig. 324.), may be introduced according to the character of the scene.

1803. Rails or fences, for parks and garden-scenery, are, as to lines, similarly characterised as gates; and, like gates, fences are of many species, from the rudest barriers without nails or iron work (fig. 327.) to the numerous sorts of iron and wire barriers. Hurdles, whether of wood or iron, are the most convenient description of temporary fences. They are manufactured of various forms and dimensions, so as to prove, as to height and openings between the rails, rods, or wires, barriers to hares, sheep, cattle, or deer. Where iron fences are considered as permanent fixtures, those parts which are inserted in the ground should be of cast-iron, as resisting oxidation much better than the wrought material. It ought, at the same time, to be covered with tar, pitch, or pyroligneous acid, or, whilst hot, painted over with oil. For interior fences, poles or laths may be formed into treillage-work of different kinds (fig. 328.); preserving the bark of the former, and pitching or charring the ends inserted in the earth.

A neat garden or lawn fence, and one which will last a long time may be made of the stems of young larch-trees. (fig. 329.)

1804. Walls are unquestionably the grandest fences for parks; and arched portals, the noblest entrances; between these and the hedge or pale, and rustic gate, designs in every degree of gradation, both for lodges, gates, and fences, will be found in the works of Wright, Gandy, Robertson, Aikin, Pocock, and other architects who have published on the rural department of their art. The pattern books of manufacturers of iron gates and hurdles, and of wire workers, may also be advantageously consulted.

Subsect. 2. Convenient Decorations.

1805. Of convenient decorations the variety is almost endless, from the prospect-tower to the rustic seat; besides aquatic decorations, agreeable to the eye and convenient for the purposes of recreation or culture. Their emplacement, as in the former section, belongs to gardening, and their construction to architecture and engineering.

1806. The prospect-tower is a noble object to look at, and a gratifying and instructive position to look from. It should be placed on the highest grounds of a residence, in order to command as wide a prospect as possible, to serve as a fixed recognised point to strangers, in making a tour of the grounds. It may very properly be accompanied by a cottage; or the lower part of it may be occupied by the family of a forester, gamekeeper, or any rural pensioner, to keep it in order, &c.

1807. The kiosque is the Chinese prospect-tower, of peculiar construction, characterised by numerous stories, designated by projecting roofs and pendant bells. An example exists at Kew, and its details will be found in the Plans of the Buildings, &c., erected there by Sir W. Chambers. Sometimes the prospect-tower is a hollow column, as in the monumental column of London, that to the memory of Lord Nelson, at Edinburgh, and to Lord Hill, at Shrewsbury; but the stairs in such buildings are necessarily too narrow for the prospect-tower of country-residences, and besides there can
be no rooms as resting-places, which are absolutely necessary, where ease and enjoyment are studied, and where some attention is had to the delicacy of women, and the frailties of old age.

1809. Temples, either models or imitations of the religious buildings of the Greeks and heathen Romans, are sometimes introduced in garden-scenery to give dignity and beauty. In residences of a certain extent and character, they may be admissible as imitations, as resting-places, and as repositories of sculptures or antiquities. Though their introduction has been brought into contempt by its frequency, and by bad imitations in perishable materials, yet they are not for that reason to be rejected by good taste. They may often add dignity and a classic air to a scene; and when erected of durable materials, and copied from good models, will, like their originals, please as independent objects. Knight, and some other connoisseurs of less note, disgusted by the abuse of temples, have argued, as it appears to us, too exclusively against their introduction, and contend for cottages as the fittest ornaments of rural scenery; but why limit the resources of an art because they are liable to abuse? Thatched roofs may become tiresome, as well as columns; and if Stow is an example of the latter carried to excess, White Knights is as certainly of the former.

1810. Porches and porticoes (fig. 330.) are sometimes employed as decorative marks to the entrances of scenes; and sometimes merely as roofs to shelter seats or resting benches.

1811. Arbors are used as summer seats and resting-places: they may be shaded with fruit-trees, as the vine, currant, cherry; climbing ornamental shrubs, as ivy, clematis, &c.; or herbaceous, as everlasting pea, gourd, &c. They are generally formed of timber lattice-work, sometimes of woven rods, or wicker-work, and occasionally of wire.

1812. The Italian arbor (fig. 332.) is generally covered with a dome, often framed of thick iron or copper wire painted, and covered with vines or honeysuckles.

1813. The French arbor (fig. 333) is characterised by the various lines and surfaces, which enter into the composition of the roof.

1814. Caves and caverns, where they exist naturally in the grounds of a residence, as at Piercefield, Corby Castle, &c., or can be readily formed, are to be regarded more as singularities or picturesque objects than as places of use or enjoyment in this climate; in Italy and Spain they are great luxuries.

1815. Grottoes are resting-places in recluse situations, rudely covered externally, and within finished with shells, corals, spars, crystallisations, and other marine and mineral productions, according to fancy. To add to the effect, pieces of looking-glass are inserted in different places and positions.
1816. *Roofed seats, boat-houses, moss houses, flint houses, bark huts,* and similar constructions, are different modes of forming resting-places containing seats, and sometimes other furniture or conveniences in or near them. Very neat buildings and furniture of this class may be formed of hazel-rods; or of any tree with a clean bark, and straight shoots, as young oaks or mountain ash. The spruce fir affords a good outside material: and five or six young trees coupled together, make good rustic columns. At White Knights, the Slopes at Windsor, and Bothwell Castle, are good examples of covered seats of the rustic kind. (*figs. 334, 335, 336.*)

1817. *Roofed seats of a more polished description* are boarded structures generally semi-octagonal, and placed so as to be open to the south. Sometimes they are portable, moving on wheels, so as to be placed in different positions, according to the hour of the day, or season of the year, which, in confined spots, is a desirable circumstance. Sometimes they turn on rollers, or on a central pivot, for the same object, and this is very common in what are called barrel-seats. In general they are opaque, but occasionally their sides are glazed, to admit the sun to the interior in winter.

1818. *Folding chairs.* A sort of medium seat, between the roofed and the exposed, is formed by constructing the backs of chairs, benches, or sofas with hinges, so as they may fold down over the seat, and so protect it from rain. After rain, when these backs are replaced in their proper position, a dry seat, and dry back to lean against, are at once obtained.

1819. *Elegant structures* of the seat kind for summer use, may be constructed of iron rods and wires, and painted canvas; the iron forming the supporting skeleton, and the canvass the protecting tegument. The mushroom or umbrella form (*fig. 337.*), and that of the Turkish tent (*fig. 338.*), the oriental pavilion, or any other exotic form free from vulgarity and meagre lines, may be made choice of on such occasions.

1820. *Exposed seats* include a great variety, rising in gradation from the turf bank to the carved couch. Intermediate forms are stone benches, root stools, sections of trunks of trees, wooden, stone, or cast-iron mushrooms painted or covered with moss, or mat, or heath; the Chinese barrel-seat, the rustic stool, chair, tripod, sofa, the cast-iron couch or sofa, the wheeling-chair, and many sub-varieties.

1821. *Swings* (*fig. 339.*), see-saws, &c. are not very common in English gardens, but, as exercising places for children, are very proper in retired, but airy parts of the pleasure-ground. Hurley-burleys, riding-wheels, &c. are better substituted by donkeys and ponies. No greater danger is incurred, and something of the art of horsemanship is thus actually acquired. In every country-residence where there are children, contrivances for their exercise and amusement ought to be considered essential objects; for these purposes, a riding school, and bath or pond for learning to swim and row a boat, may be considered essential. The former may also serve for acquiring the infantry and cavalry exercise, and learning to fire at a mark, jump, run, wrestle, box, climb trees or smooth poles, ascend ropes, &c.
1822. Of constructions for displaying water, as an artificial decoration, the principal are cascades, waterfalls, jets, and fountains. The foundation of the cascade and waterfall, is the head or dam which must be thrown across the river or stream; and in this, two things are to be considered, its strength, and the materials of which it is composed.

1823. With respect to strength, the pressure of water is as its depth, and consequently a dam, whose section is a right-angled triangle (fig. 340. a, b, c), and whose hypothenuse (a, b) forms an angle of 45°, with the base (a, c) formed of any material of greater specific gravity than water, would, as far as strength is concerned, hold in equilibrium a body of still water of a depth equal to its perpendicular. If the hypothenuse, or sloping side, be placed next the water, it will more than hold the water in equilibrium, by the weight of the triangle (a, b, d) of the water superincumbent on the triangle of the dam or bank.

1824. That the materials of the bank must be of a nature impervious to water, and also must adhere to the base or bottom, so as not to admit water to escape beneath it, are obvious conditions of the foregoing proportion. The practice of forming dams or heads, is derived from this theory; but to guard against accident, the base of the triangle is always made three or more times greater than its height; the slope next the stream may form an angle with the horizon, of from 40° to 20°, and that on the lower side is regulated by the uses of the dam. If for raising water so as to cover a hollow where there is little or no overflow expected, then the slope is generally of earth, 40° or 35° (fig. 340. e, f), turfed or planted; if for a cascade, the slope is regulated by the form or undulations on which the rocks to produce the breaking of the water are to be placed; and if for a waterfall, a perpendicular wall is substituted, over which the water projects itself in a sheet or lamina, in breadth proportioned to the quantity of the current.

1825. In all these cases, instead of forming the dam entirely of materials impervious to water, it is sufficient if a vertical stratum of wrought-clay be brought up its centre (fig. 340. g, f), and the surface of the bank rendered firm by a coating of gravel on the slope next the water.

1826. The construction of the waterfall, where avowedly artificial, is nothing more than a strong-built wall across the stream, perfectly level at top, and with a strong, smooth, accurately fitted, and well jointed coping. On the perfection of the coping, both as to level and jointing, depends the regular distribution of the lamina of water to be projected. Formerly artificial cascades of this sort were curved in the ground-plan, the concavity pointing down the stream, by which some strength and a better view of the water were supposed to be obtained. With respect to strength, this can only hold true, or at least be of consequence, in cases where the upper slope of the dam is very steep, and the force of the current great; and as to a fuller view, this can only take place when the eye of the spectator is in the focus of the segment. Where a natural waterfall is to be imitated, the upright wall must be built of huge irregular blocks; the horizontal lamina of water broken in the same way by placing fragments of rocks grouped here and there so as to throw the whole into parts; and as nature is never methodical, to form it as if in part a cascade.

1827. In imitating a natural cascade in garden-scenery, the horizontal line must here also be perfect, to prevent waste of water in dry seasons, and from this to the base of the lower slope the surface must be paved by irregular blocks, observing to group the prominent fragments, and not distribute them regularly over the surface. In the infancy of landscape-gardening, the lower bank or slope of the dam was formed into ogee and other curves, or a serpentine line, and smoothly paved or causeyed, fixing on the convexities of the curves projecting boards across the current; and the current being thus interrupted, was thrown up in arched waves. Such was the sort of beauty then admired; for it is a long time in the progress of improvement before man can see any other beauty than that which he has himself produced.

1828. The greatest danger in imitating cascades and waterfalls, consisting in attempting too much, a very few blocks, disposed with a painter's eye, will effect all that can be in good taste in most garden-scenes; and in forming or improving them in natural rivers, there will generally be found indications both as to situation and style, especially if the country be uneven, or stony, or rocky. Nothing can be in worse taste than piles of stones and rocks across a river either natural or artificial, in a tame alluvial meadow: they may be well chosen fragments from suitable materials, and arranged so as to form a cascade or waterfall very beautiful of itself, but whose beauty is really deformity or mon-
strosity, relatively to the surrounding scenery, or to that whole of which it should form an accordant part.

1829. *Jets and other hydraulic devices*, though now less in repute than formerly, are not to be rejected in confined artificial scenes, and form an essential decoration where the ancient style of landscape is introduced in any degree of perfection.

1830. The *first requisite for jets or projected spouts, or threads of water*, by atmospheric pressure, is a sufficiently elevated source or reservoir of supply. This being obtained, pipes are to be conducted from it to the situations for the jets. No jets, however constructed, will rise as high as the fountain-head; because the water is impeded by the resistance of the air, the friction against the opening of the pipe or adjutage, and its own gravity. It is not easy to lay down data on this head; if the bore of the adjutage be too small, the rising stream will want sufficient weight and power to divide the air, and so being dashed against it will fall down in vapor or mist. If too large, it will not rise at all. The length of pipe between the reservoir and the jet will also impede its rising in a slight degree by the friction of the water on the pipe. This is estimated by P. J. Francois (*Art des Fontaines*, 137.) at one foot for every hundred yards from the reservoir. The proportion which this author gives to the adjutages relatively to the conducting-pipes, is one fourth; and thus for a jet of four lines, or a third of an inch, he requires an adjutage of between four and five lines, and a conducting pipe of one inch and a half diameter; for a jet of six or seven lines, a conducting-pipe of two inches, and so on. From these data, the height of the fountain and the diameter of the conducting-pipe being given, the height to which a jet can be forced can be estimated with tolerable accuracy, and the contrary. But where the pipes are already laid, and the power of the head, owing to intervening obstructions, not very accurately known, the method by trial and correction by means of a leaden nozzle, the orifice of which may be readily increased or diminished, will lead to the exact power under all the circumstances.

1831. *Adjutages* are of various sorts. Some are contrived so as to throw up the water in the form of sheaves, fans, showers, to support balls, &c.; others to throw it out horizontally, or in curved lines, according to the taste of the designer; but the most usual form is a simple opening to throw the spout or jet upright. The grandest jet of any is a perpendicular column issuing from a rocky base, on which the water falling, produces a double effect both of sound and visual display. A jet rising from a naked tube in the middle of a basin or canal, and the waters falling on its smooth surface, is unnatural, without being artificially grand.

1832. *Dropping fountains* (*figs. 341, 342, 343.*), overflowing vases, shells (as the chama gigas), cisterns, sarcophagi, dripping rocks, and rockworks, are easily formed, requiring only the reservoir to be as high as the orifice whence the dip or descent proceeds. This description of fountains, with a surrounding basin, are peculiarly adapted for the growth of aquatic plants. Both classes of water-works successfully combine.

1833. *Waste-drains.* In all water-works in gardens, pipes or drains must be contrived to carry off such of the water as is not used in culture. The diameter of these should be somewhat larger than the conducting-pipes, for obvious reasons.

1834. *Sun-dials* are venerable and pleasing garden-decorations; and should be placed in conspicuous frequented parts, as in the intersection of principal walks, where the "note which they give of time" may be readily recognised by the passenger. Elegant and cheap forms are now to be procured in cast-iron, which, it is to be hoped, will render their use more frequent.

1835. *Vanes* are useful in the same way, but are an unsuitable garden-ornament, though frequently introduced on the summits of garden-buildings. The ideas to which they give rise, as connected with ships, flags, fairs, military standards, &c. are all opposite to the stillness and repose of gardens. Over a library or office they are useful, connected with an internal index; and they are characteristic and proper over churches, family-chapels, clock-towers, and domestic offices.
SUBJECT. 3. Characteristic Decorations.

1836. As characteristic decorations are purely decorative, without any pretensions to convenience, they should ever be very sparingly employed, and only by persons of judgment and experience. A tyro in gardening will be more apt to render himself ridiculous by the use of decorations, than by any other point of practice, and most apt by the use of characteristic decorations.

1837. Rocks are generally considered as parts of the foundation of the earth, and their general character is that of grandeur, sometimes mixed with the singular, fantastic, or romantic. Their expression forms a fine contrast to that of perishable vegetation, and therefore they have been eagerly sought after in gardens, both on this account, and as forming a suitable habitation for certain descriptions of plants. Plant-rockworks are protuberant surfaces, or declivities irregularly covered with rocky fragments, land-stones, conglomerated gravel, vitrified bricks, vitrified scoria, flints, shells, spar, or other earthy and hard mineral bodies. Such works are, in general, to be looked on more as scenes of culture than of design or picturesque beauty.

1838. Rockworks for effect or character require more consideration than most gardeners are aware of. The first thing is to study the character of the country, and of the strata of earthy materials, whether earth, gravel, sand, or rock, or a mere nucleus of either of these, such as they actually exist, so as to decide whether rocks may, with propriety, be introduced at all; or, if to be introduced, of what kind, and to what extent. The design being thus finally fixed on, the execution is more a matter of labor than of skill.

1839. The ruins of objects adapted by their natures or constructions to brave time, have always excited veneration; and this sentiment, forming a contrast with those emotions raised by mere verdant scenes, has ever been esteemed very desirable in gardens. Hence the attempt to produce them by forming artificial ruins, which, being absolute deceptions, cannot admit of justification. If any thing is admissible in this way, it is the heightening the expression of ruins which already exist, by the addition of some parts, which may be supposed to have existed there when the edifice was more entire. Thus, the remains of a castle-wall, not otherwise recognisable from that of a common house or enclosure, may be pierced with a window or a loophole, in the style appropriate to its date, or it may be heightened or extended in some degree. In other cases, turrets, or pinnacles, or battlements, or chimney-tops may be added according to circumstances, and as a judicious and experienced taste and antiquarian architect may direct. Unless the style of the age of the ruins be adopted, the additions become worse than useless to all such as are conversant in the history of architecture, of which an example may be given in the modern Gothic turrets, in the grounds of White Knights, intended to represent the abbey of that name, founded soon after the Norman conquest.

1840. Antiquities (fig. 344.) are nearly allied to ruins, but differ from them in being of some value as objects, independently of locality. They may be valuable from their great age, as druidical; from historical traditions connected with them, as stones indicating the site of a battle, the cross-stone of an ancient town, &c.; or from the excel-
lence of the workmanship or the material, as in the fragments of Grecian and Roman sculpture and architecture. This class of decorations is very common in Italy, and especially near Rome and Naples. Viewed as parts of landscape, almost every thing depends on their union with the surrounding scenery.

1841. Rarities and curiosities, like antiquities, possess a sort of absolute value; but the sentiments to which they give rise are more allied to wonder than veneration. They are occasionally introduced in gardening, such as the jaw-bones of the whale, basaltic columns, lava blocks, pillars of earthy rock-salt. The tufa, corals, and madrepores brought from Otaheite by Captain Cook, as ballast, now form part of the rock work in the Chelsea garden. Chinese rocks, idols, and other Chinese garden-ornaments, are sometimes admitted, not as imitations of rocks or sculpture, but as curiosities.

1842. Monumental objects, as obelisks, columns, pyramids, may occasionally be introduced with grand effect, both in a picturesque and historical view, of which Blenheim, Stow, Castle Howard, &c. afford fine examples; but their introduction is easily carried to the extreme, and then it defeats itself, as at Stow. In this department may be truly said, after Buonaparte, "Du sublime au ridicule il n'y a qu'un pas!"

1843. Sculptures. Of statues, thermes, busts, pedestals, altars, urns, and similar sculptures, nearly the same remarks may be made. Used sparingly, they excite interest, often produce character, and are always individually beautiful, as in the pleasure-grounds of Blenheim, where a few are judiciously introduced; but profusely scattered about, they distract attention.

1844. Vegetable sculptures (fig. 345.) are very appropriate in parterres and other scenes in the ancient style. That they may be executed with correctness and without loss of time, the skeleton should be formed of wire, within which all the shoots should be confined, and when once the form is filled up with vegetation, the gardener has only to clip the protruding shoots. Groups of figures of different colors may be very curiously executed by using different colored greens. In the garden of the convent of the Madre di Dio, near Savonna, is a group representing the flight of Joseph into Egypt, in yellow box, variegated holly, myrtle, cypress, laurel, and rosemary. The attending priest told us these plants completed their forms in three years.

1845. Inscriptions, as historical records, without comment, may in some cases be admissible; as the date when any work was begun and finished, the height of elevated points above the level of the sea, or relatively to other surrounding elevated and conspicuous objects, &c. &c.; but sentimental and religious inscriptions cannot be approved of by men in general. They are something superadded to what is or ought to be already complete, and place nature in the situation of the painter, whose portraits required the aid of graphical description. "This is a black bear." That is "A happy rural seat of various view."

1846. Eje-traps, painted perspectives, on walls or boards, as terminations, mock hermits, soldiers, banditti, wooden lions (as at Hawkstone), sheep in stucco, or any other figures of men or animals, intended to pass for realities, though still used in Holland and France, may be pronounced as too puerile for the present age. If they are still admired by the city mob in a suburban tea-garden, so much the better; the mob must be pleased as well as their superiors, and the rich vulgar may join with them; but the object of all the arts, whether useful or agreeable, is to elevate our tastes and enjoyments; and therefore as soon as men's minds are prepared for any refinement on former things, the particular art to which these things belong should prepare the way for their removal, by presenting appropriate substitutes. A few reading tents and portable coffee-houses scattered over the public parks round London and Edinburgh, as at Paris and Vienna, in umbrageous and picturesque situations, would be fitting resources for one class of pedestrians, as those crowded yards called tea-gardens are for others.

---

**Chap. IV.**

**Of the Improvement of the Mechanical Agents of Gardening.**

1847. The greater number of the implements and buildings enumerated in the foregoing chapters may no doubt be done without, even in the first-rate gardens. A number more, however, might have been added, which are in use in particular situations and circumstances, but we have omitted them, some as not meriting to become general, and
others because their forms or constructions were too obsolete for modern practice, or too new and imperfect in construction to merit recommendation. A gardener of science and experience is not to be confined in his choice to what is or has been in this or in any department of his art; but drawing from the resources of his own mind, he may, and ought not only to improve what is already in use, but design and get executed, new tools, instruments, and constructions, better calculated to effect the ends in view generally, or more suited to the exigencies of his particular case. Notwithstanding the alterations and ameliorations which have of late been so frequently made, there are few of the mechanical agents of gardening now in use, that do not admit of some, and many of them, unquestionably, of much improvement. The ultimate effect of all these ameliorations is to lessen human labor, and increase the quantity, or improve the quality, of garden-productions, so that every attempt to extend them is highly meritorious.

1848. As a general principle in respect to implements, structures, and buildings, the best designs should be selected, and their execution procured in the best manner and of the best materials. This can scarcely be too strongly impressed on the mind of the gardener or his employer. With tools or instruments made of improper timber or iron, and of indifferent workmanship, the operator can never satisfy himself or his master. The quantity of his labor is less, and the quality inferior; add to this, that the instrument soon begins to decay, and requires to be renewed, so that independently altogether of the loss in the quantity and quality of labor, the loss occasioned by the renewal of the tool, instrument, or machine, ought to be a sufficient inducement to procure at first only the very best. The true way to ensure this, where the party are not judges, is to employ tradesmen of good repute and long standing. In general, seedsmen should be the persons from whom all the implements of gardening ought to be procurable; but as they often omit this branch of their business, from the want of regular demand, recourse must be had to ironmongers, or to those new establishments called Horticultural and Agricultural Repositories.

1849. Hot-houses are by far the most important class of garden-structures. With respect to them, no degree of horticultural skill and practical attention will compensate for the want of light or air, or a bad exposure; and where the arrangements for supplying artificial heat are imperfect, the risk is great, and painful for a zealous gardener to contemplate. One night may destroy the labors of the past year, and forbid hope for the year to come; the blame may be laid where it is not merited, and a faithful servant may lose his situation and his character, without having committed either errors of ignorance or carelessness.

1850. In all structures and edifices, the most complete, elegant, or grand design, when badly executed, is disagreeable to the view, defective in the object of its erection, and ruinous to the proprietor. Bad foundations and roofs, improper materials, materials of different degrees of durability, piled incongruously together, and bad workmanship form the elements of bad execution. In no country are materials and labor obtained in greater perfection than in England; and in all regular works coming under the architect or the engineer, we generally find little to condemn, and often much to admire in the execution of the work. Garden-buildings, however, and especially that important class, hot-houses, are, relatively to civil architecture, an anomalous class of structures; and hence they are more the subject of chance or caprice in design, and of local convenience in execution, than those of any department of rural architecture. The subject of horticultural architecture, indeed, till very lately, has not been deemed of sufficient importance, to induce an architect to make himself master of the first step towards improvement in every art, the knowledge of what has already been done in it by others. Hence it follows, that garden-buildings, and especially hot-houses, are left either wholly to gardeners, who understand little of the science of architecture, or wholly to architects, who understand as little of the science of gardening. The consequence in either case, generally is, incongruity in appearance, want of success in the useful results, and want of permanency in duration. It would be more easy to adduce examples than to avoid the charge of impartiality in the selection.

1851. The recent improvements in the manufacture of iron, and the war-price of timber, have greatly extended the use of the former material in most erections, and contributed, from the novelty of the thing, to a good deal of incongruity in the disposition of the materials of buildings. Thus we have cast-iron sashes in deal frames, cast-iron rafters placed on timber wall-plates, iron bars sheathed with copper, and many such discordant arrangements, certain in the end of defeating the purpose for which they were adopted.

1852. Artists. There are two modes which proprietors may adopt who are desirous of embodying in garden-erections the modern improvements. The first is, to employ a first-rate head gardener, and to authorise and require of him, to consult with a regular architect or engineer, previously to fixing on any plan for a structure or machine; and the second is, to employ a regular garden-architect. A connoisseur will, no doubt, think
for himself, and form his own plans; and a spirited amateur will be the first to adopt new improvements; but the policy of a well regulated man, who has no pretensions to particular skill himself, will certainly lead him to adopt one of the two first modes.

BOOK IV.
OF THE OPERATIONS OF GARDENING.

1853. All the operations of gardening are mechanical in the first instance, though the principal intention of many of them is to effect chemical changes, and of others, changes on the vital principle. They are also all manual, or effected by man, who, though possessing little power over nature in his naked, unarmèd state, yet taking in his hands some one of the implements or machines described, becomes thereby armed with a new power, and operates on the soil, or on the vegetable itself, by effecting changes in his own centre of gravity, and by muscular movements of his legs and arms, calculated by pushing, drawing, or lifting, to bring the implement into the action proper for performing the operation in view. All these movements are governed by the laws of mechanics, and the operations performed, are all referable to one or more of the mechanical powers, and chiefly, as we have before observed, to the lever and the wedge.

1854. The operations of gardening present astonishing proofs of the advanced state of the art. In the infancy of gardening, as the implements were few, so would be also the operations of culture. The ground would be loosened on the surface with a hooked stick (Fig. 2.), or scratched with a bone, or a horn in the spring season; the plants or seeds rudely inserted, and the produce in autumn broken over or pulled up, as wanted by the family or band to whom they belonged. But in the present state of human improvement, the operations of gardening have branched out into a number and variety which at first sight appear astonishing. The operations of pulverisation and sowing, for example, are not confined to spring; but are practised in every month of the year. The season of reaping or gathering crops is equally extended; and for such productions as cannot be produced or preserved in the open air, recourse is had to hot-houses, and fruit and root store-rooms. Vegetation is accelerated, retarded, and modified, almost at the will of the operator; and by processes which suppose a considerable degree of physiological and chemical science, as well as practical skill, mechanical dexterity, and personal attention. Thus, shading, airing, and watering, though operations exceeded by none in manual simplicity, cannot be performed without continual reference to the state of the plant, of the soil, and of the climate or weather. Hence it is, that an operative gardener who really knows his profession, requires to be not only a háble workman, but a thinking and reasoning being, and a steady man. We shall consider the operations of gardening, 1. As consisting of operations or labors in which strength is chiefly required; 2. As operations where skill is more required than strength; and, 3. As operations or processes where strength, skill, and science, are combined.

CHAP. I.

Operations of Gardening, in which Strength is chiefly required in the Operator.

1855. To acquire the practice of gardening-operations, a few hours' labor with the implements or machines will be of more use than a volume of words; all that we shall submit, therefore, will be some observations relatively to the mechanical action of the implement and operator, the object of the operation, and the best season of performing it. They may be arranged as, 1. Mechanical operations common to all arts of manual labor; 2. Garden-labors on the soil; and, 3. Garden-labors on plants.

SECT. I. Mechanical Operations common to all Arts of Manual Labor.

1856. All the operations which man performs with implements or machines are, as far as his own person is concerned, reducible to lifting, carrying, drawing, and thrusting. Man himself, considered as an engine, derives his power from alterations in the position of his centre of gravity, and he applies it chiefly by his hands, arms, and legs acting as levers of the third kind.

1857. Lifting is performed by first stooping or lowering the centre of gravity, and at the same time throwing it to one side. The object being then laid hold of by the hands, the body is raised, and the centre of gravity, in being restored to its true position, acts as a counterbalancing weight to the weight to be raised. The weight retained by
the hand is now raised a certain height, never exceeding half that of the man; if to be raised higher, recourse is had to muscular strength, or the power of the arms to act as levers.

1858. Carrying. To carry a thing is merely to walk with a greater weight than before, and walking is performed by a series of alternate derangements and adjustments of the centre of gravity, slow or rapid, according as the person may walk or run. According to Delohm, the most advantageous weight for a man of common strength to carry horizontally is 112 lbs.; or, if he returns unladen, 135 lbs.

1859. Drawing. In this operation, the upper part of the body is thrown forward, so as to act as a power to counterbalance or lift up the body or weight to be moved; and by joining to this lifting motion the operation of walking, the weight is at once lifted up and drawn along. This compound operation is exemplified in a horse, when straining at a draught in a plough or cart. He first lowers his chest, then raises it, and lastly steps forward. When drawing at ease, the lifting motion is scarcely distinguishable from the progressive one.

1860. Pushing or thrusting is performed exactly on the same principles as drawing, and differs from it chiefly in the kind of implement or machine which requires to be employed; all machines which are to be pushed requiring to be attached to the animal machine by parts acting by their rigidity; whereas, those to be drawn may be attached by parts acting by their tenacity merely.

1861. All these operations may be varied in quantity, either by a variation in the weight or gravity of the man, or moving power; or by a variation in the time or rapidity of his motions. Thus a heavy man may, in one movement, lift a weight ten times greater than can be done by one of less weight; but a light man may, by increasing the time of performance, lift the same weight at ten times. A man, who in digging can apply with his feet five cwt. of his weight towards pushing the wedge or blade of the spade into the soil, has an evident advantage over a lighter man who can only apply three cwt. for that purpose; but yet the latter may equal the former, by accompanying his power or foot with a proportionate increase of motion. The power in this last case is said to be obtained by the momentum, or quantity of matter in a body multiplied by the velocity with which it is moved. Power, therefore, we thus ascertain, is obtained by matter and motion jointly, and what may be deficient in the one, may be made up by excess in the other. Thus, a small, light workman may (though with more animal exertion) produce as much work as a larger or heavier man: for if we suppose the quantity of matter in the large man to be thirty, and his motion at the rate of two, then if the quantity of matter in the small man be twenty, and his motion at the rate of three, he will produce an equal effect with the large man. As small human machines, or little men, are generally constructed of firmer materials, or more healthy and animated, than large ones, the small man performs his rapid motions with nearly as great ease to himself as the heavy man moves his ponderous weight; so that in point of final result they are very nearly on a par.

Sect. II. Garden-labors on the Soil.

1862. The simple labors peculiar to arts of culture are performed either in the body of the soil, as picking, digging; on its surface, as hoeing, raking; or on vegetables, as cutting, clipping, &c.

1863. Picking. The pick, as we have seen (fig. 77.) is a blunt wedge, with a lever attached to it at right angles, and the operation of picking consists in driving in the wedge perpendicularly, so as to produce fracture, and then causing it to operate horizontally by the lever or handle, so as to effect separation, and thus break up and loosen hard, compact, or stony soils. It is also used to loosen stones or roots; and the pick-axe is used to cut the latter. For breaking and pulverising the soil, the most favorable conditions are, that the earth should be moderately moist, to facilitate the entrance of the pick, but in tenacious soils not so much as to impede fracture and separation.

1864. Digging. The spade is a thin wedge, with a lever attached in the same plane, and the operation of digging consists in thrusting in the wedge by the momentum (or weight and motion) of the operator, which effects fracture; a movement of the lever next effects separation, whilst the operator, by stooping and rising again, lifts up the spittle or section of earth on the blade or wedge of the spade, which, when so raised, is dropped in a reversed position, and at a short distance from the unbroken ground. The separation between the dug and undug ground is called the trench or furrow; and when a piece of ground is to be dug, a furrow is first opened at that end of it where the work is to commence, and the earth carried to one end where it is to terminate, where it serves to close the furrow. In digging, regard must be had to maintain a uniform depth throughout; to reverse the position of each spittle, so as what was before surface may now be buried; to break and comminute every part where pulverisation is the leading object; to preserve each spittle as entire, and place it separate, or isolated as
much as possible where aeration is the object; to mix in manures regularly where they are added; to bury weeds not injurious; and to remove others, and all extraneous matters, as stones, &c. in every case. For all these purposes a deep open trench is requisite, and that this may not be diminished in the course of the operation, it must never be increased in length. If allowed to become crooked by irregular advances in the digging, it is thus increased in length, and necessarily diminished in capacity, unless, indeed, the dug ground is allowed to assume an uneven surface, which is an equally great fault.  

1865. Weather for the operation. Digging, for pulverisation and mixing in manures, is best performed in dry weather; but for the purposes of variation, a degree of moisture and tenacity in the soil is more favorable for laying it up in lumps or entire pieces. The usual length of the blade of a spade is from ten inches to a foot, but as it is always inserted somewhat obliquely, the depth of pulverisation in gardens attained by simple digging seldom exceeds nine inches, and in breaking up firm grounds it is seldom so much.  

1866. Shovelling is merely the lifting part of digging, and the shovel being broader than the spade, is used to lift up fragments separated by that implement or the pick.  

1867. Excavating is the operation of working out pits, furrows, or other hollows in grounds, either for the commencement of other operations, as digging or trenching, or for planting, burying manures, inserting roots; or on a large scale, for forming pieces of artificial water, &c.  

1868. Levelling, in the ordinary sense of the term, as used in gardening, consists in spreading abroad the soil in such a way that its surface may be nearly in one uniform plane, either level or nearly so; to be correct, this plane ought to be parallel with that of the horizon; but very generally an even surface, if not very far from level, answers all its purposes. The terms level and even, in ground-work, however, ought to be considered as quite distinct: the former should be like the surface of still water, and the latter merely free from inequalities.  

1869. Marking with the line is an operation preparatory to some others, and consists in stretching and fixing the line or cord along the surface by means of its attached pins or stakes, in the direction or position desired, and cutting a slight continuous notch, mark, or slit in the ground, along its edge with the spade.  

1870. Trenching is a mode of pulverising and mixing the soil, or of pulverising and changing its surface, to any greater depth than can be done by the spade alone. For trenching, with a view to pulverising and changing the surface, a trench is formed like the furrow in digging, but two or more times wider and deeper; the plot or piece to be trenchèd is next marked off with the line into parallel strips of this width; and beginning at one of these, the operator digs or picks the surface stratum, and throws it in the bottom of the trench. Having completed with the shovel the removal of the surface stratum, a second, and a third, or fourth, according to the depth of the soil and other circumstances, is removed in the same way; and thus, when the operation is completed, the position of the different strata is exactly the reverse of what they were before.

In trenching, with a view to mixture and pulverisation (fig. 346.), all that is necessary is to open, at one corner of the plot, a trench or excavation of the desired depth, three or four feet broad, and six or eight feet long. Then proceed to fill this excavation from one end by working out a similar one. In this way proceed across the piece to be trenchèd, and then return, and so on in parallel courses to the end of the plot, observing that the face or position of the moved soil in the trench must always be that of a slope, in order that whatever is thrown there may be mixed, and not deposited in regular layers, as in the other case. To effect this most completely, the operator should always stand in the bottom of the trench, and first picking down and mixing the materials, from the solid side (a), should next take them up with the shovel, and throw them on the slope or face of the moved soil (b), keeping a distinct space of two or three feet between them. For want of attention to this, in trenching new soils for gardens and plantations, it may be truly said that half the benefit derivable from the operation is lost. In general, in trenching, those points which were mentioned under digging, such as turning, breaking, dunging, &c. require to be attended to, and sometimes an
additional object, that of producing a level from an irregular surface is desired. In this case double care is requisite to avoid forming subterraneous basins or hollows, which might retain water in the substratum, at the bottom of the moved soil, and also to mix inferior with better soil, &c. where it becomes requisite to penetrate into depositions of inferior earthy matters.

1871. **Ridding** is a mode of finishing the surface, applicable either to dug or trenched grounds, which, when so finished, are called ridge-dug or ridge-trenched. Instead of being formed with an even surface, ridged grounds are finished in ridges, or close ranges of parallel elevations, whose sections are nearly equilateral triangles. Hence, supposing the triangles to touch at their bases, two thirds more of surface will be exposed to the influence of the atmosphere and the weather, than in even surfaces.

1872. **Forking.** The fork is composed of two or three separate, parallel, and uniform wedges, joined so as form one general blade, which is acted on like the spade, by means of a shoulder or hilt, for thrusting it into the matters to be forked, and a lever or handle for separating and lifting them. In gardening, forking is used for two purposes; for pulverising the soil among growing crops, and for moving vegetable manures. In the first case the operation is similar to digging, the only difference being that pulverisation is more attended to than reversing the surface; in the other, the fork separates chiefly by drawing and lifting; hence for this purpose a round-pronged (or dung) fork (fig. 85.) produces least friction during the discharge of the forkful and reinsertion; and in the other a broad-pronged (or garden) fork (fig. 86.) separates and lifts the soil more readily. Dry weather is essentially requisite in forking soils, and most desirable for spreading manures; but dunghills may be turned, and hot-beds built, during rain, with no great injury.

1873. ** Hoeing ** is performed by drawing or thrusting the wedge or blade of the draw or thrust hoe along the surface of the soil, so as to cut weeds at or under the surface, and slightly to pulverise the soil. It is used for four purposes, sometimes together, but commonly separate; first, to loosen weeds so as they may die for want of nourishment, or be gathered or raked off, for which purpose, either the thrust or draw hoe may be used; the second, to stir the soil, and for this purpose, when no weeds require killing, the pronged hoe is preferable, as being thrust deeper with less force, and as likely to cut the roots of plants; the third, is to draw up or accumulate soil about the stems of plants, for which purpose a hoe with a large blade or shovel will produce most effect; and the fourth is to form a hollow gutter or drill, in which to sow or insert the seeds of plants, for which a large or small draw-hoe may be used, according to the size of the seeds to be buried. The use of the hoe for any of the above purposes requires dry weather.

1874. ** Raking ** is performed by drawing through the surface of the soil, or over it, a series of small equilateral wedges or teeth, either with a view to minute pulverisation, or to collecting weeds, stones, or such other extraneous matters as do not pass through the interstices of the teeth of the rake. The teeth of the rake being placed nearly at right angles to the handle, it follows that the lower the handle is held in performing the operation, the deeper will be the pulverisation, and on the contrary, that the higher it is held, the interstices being lessened, the fewer extraneous matters will pass through the teeth. The angle at which the handle of the rake is held must therefore depend on the object in view; the medium is forty-five degrees. For all raking, except that of new-mown grass, dry weather is essentially requisite.

1875. ** Cuffing ** is a mode of excavating used in preparing a surface for seeds, and in covering them when sown; the surface being well pulverised by digging and raking, is laid out into beds with alleys between, at least three times the breadth of the operator's foot. Then take a wooden-headed or cuffing-rake (1314.), stand on the alley of the opposite side of the bed; turn the rake on its back, and push off the earth from the one half of the bed to the purpose depth, as far as the side of the alley marked by your feet, being careful to keep the earth so pushed off quite straight. When one side is finished, turn round and do the other in the same manner. After the seeds are sown take the rake, stand on the alley on the opposite side of the bed; put in the teeth of the rake immediately beyond the cuffing or ridge of earth pressed off, and, by a sudden pull, draw it on the bed so as to cover its own half equally. And having finished this half, turn round, and finish the other in the same manner; and the operation is completed. (Sang's. *Plant. Kal.* 242.)

1876. ** Scraping ** is drawing a broad and blunt wedge along hard surfaces, in gardening generally those of lawns or walks, to remove excrementitious matters thrown out of the soil by worms. Moist weather best suits the operation on lawns, and dry weather on gravel.

1877. ** Sweeping, ** mechanically considered, is the same operation as scraping. In gardening, it is chiefly used after moving, and for collecting leaves; for both which purposes dewy mornings are preferable, as at such seasons the leaves or grass being moist, conglomerate without adhering to the dry soil.
1878. *Wheeling* is a mode of carrying materials in which the weight is divided between the axle of the wheel and the arms of the operator. The arms or shafts of the barrow thus become levers of the second kind, in which the power is at one end, and the fulcrum at the other, and the weight between them. The weight is carried or moved on by the continual change of the fulcrum with the turning of the wheel; and this turning is produced by the operator throwing forward his centre of gravity so as to push against the wheel by means of the moveable axle, &c. The chief obstacles to wheeling are the roughness or softness of the surface to be wheeled on. Where this is firm, there wheeling will be best performed with the greater part of the load resting on the axle; but when soft and deep, the centre of gravity should be nearest the operator, who will find it easier to carry than to overcome excessive friction. Dry weather is obviously preferable for this operation. "With wheelbarrows," Dr. Young observes, "men will do half as much more work as with hods."

1879. *Beating* is the application of pressure to surfaces or to materials, with a view to render them more fit for particular uses. Thus, in new-laid turf verges, or gravel alleys, compactness and adhesion are required and obtained by beating; in working clay for puddling or claying the bottom of ponds or cisterns, intimate mixture, exclusion of air, and of hard particles, are effected by the same means.

1880. *Rolling* is the application of pressure to surfaces on a large scale, and chiefly to turf and gravel. The roller, mechanically considered, is the second mechanical power, or wheel and axle, to which the handle becomes a lever of the second kind, as in the wheelbarrow. The amount of its action is as the breadth of the wheel and joint weight of it and of the axle; it is drawn over the surface, and produces by far the greatest effect when the ground is saturated with moisture below, but dry on the immediate surface.

1881. *Sifting* or *screening* are operations for separating the coarser from the finer particles of earth, gravel, tanners' bark, &c. The materials require to be dry, well broken, and then thrown on the screen (fig. 1392.), where being a sliding inclined plane, in sliding down it, the smaller materials drop through while the larger pass on. In sifting, the same process is effected, by motion with a sieve or circular and flat grating of limited extent. The screen is calculated for coarser operations, as with gravel and bark on a large scale, and the sieve for finer operations with plant-moulds and composts.

### Sect. III. Garden-labors with Plants.

1882. *The simple operations performed on vegetables* are sawing, cutting, clipping, splitting, mowing, and weeding.

1883. *Sawing.* The saw is a conjoined series of uniform wedges, which, when drawn or thrust in succession across a branch or trunk gradually wear it through. In performing the operation, the regularity of the pressure and motion are chiefly to be attended to.

In green or live shoots, the double-toothed saw produces less friction on the sides of the plate, by opening a larger channel for its motion. Where parts are detached from living trees, the living section ought generally to be smoothed over with a knife, chisel, or file; and a previous precaution in large trees is to cut a notch in the lower part of the branch immediately under and in the line of the section, in order to prevent any accident to the bark, when the amputated part falls off. Sawing is a coarser mode of cutting, mowing, or shaving; or a finer mode of raking, in which the teeth follow all in one line.

1884. *Cutting* is performed by means of a very sharp wedge, and either by drawing this through obliquely or across the body to be cut, as in using the knife; or by pressing or striking the axe or hedge-bill obliquely into the body, first, on one side of an imaginary line of section, and then on the other, so as to work out a trench across the branch or trunk, and so effect its separation. The axe, in gardening, is chiefly used in felling trees, and for separating their trunks, branches, and roots into parts. The knife is extensively used for small trees, and the hedge-bill and chisel for those of larger size. In amputating with the knife, one operation or *draw-out* ought generally to be sufficient to separate the parts; and this ought to be made with the knife sufficiently sharp, and the motion so quick as to produce a clean, smooth section, with the bark uninjured.

1885. Every *draw-out* produces a smooth section, and a fractured or bruised section; and one essential part of cutting living vegetables, is to take care that the fractured section be on the part amputated. Another desirable object is, that the section of the living or remaining part should be so inclined (a, fig. 347.) as not to lodge water or overflowing sap, and so far turned to the ground (d) or to the north, as not to be struck by the direct rays of the sun. To accomplish both these purposes, as well as to make sure of having the fractured section on the part amputated, the general practice is to cut from below or from the under edge of the branch or shoot, unless the position of the leading bud occasions a deviation from the rule (b). The cut should also be made in all shoots of not more than three or four years old, within from one fourth to half an inch, or a little more of the bud intended to take the lead; when this is not done, and half an inch or more of
shoot left without a bud (c and e), the consequence is, the stump dies back to the bud in the course of the season (g), and if not carefully cut off (f), will end in a decaying orifice both unsightly and injurious. The bud selected for a leader ought always to be a leaf-bud, and in general the plane of the section ought to be parallel to the angle which the bud makes with the stem (d). Exceptions occur in the case of plants with much pith (h), as the vine, elder, &c. in cutting the year-old shoots of which, an inch or more ought to be left, as these always die back a few lines; and thus the leading bud might be injured, if this precaution were not taken. In like manner, when pruning a large tree, the section of amputation ought to be made so oblique as to throw off the rain; as generally as possible, it should be turned from the sun, and rather downwards than upwards, in order to shield it from heat and cracking: and whenever it can be done, it should be made near a branch, shoot, or bud, which may take the lead in the room of that cut off, and thus, by keeping the principle of life in action at the section, speedily heal up the wound.

1886. In pruning roots, the same principle, as far as applicable, ought to be attended to; the trunk or stem when cut over ought to be sloped to the north (i), and the lateral roots cut so as the section may be on the under side (k), and therefore less likely to rot than when the cut faces the surface of the ground (o), or is bruised by neglecting to form the smooth section on the attached extremity. When roots are large always cut to a lateral, and when they are small to a fibre; for in roots as in shoots, naked extremities always die back to the nearest leader. When a root broken or bruised lies neither laterals nor fibres, then merely cut back to sound wood, leaving a smooth section; for the sap which always operates first and most powerfully at the extremities both of roots and shoots, will there originate fibres.

1887. In cutting with the chisel, the blade is applied below the branch to be amputated, so as to rest on the trunk or main branch, and so applied, a quick blow with a mallet is applied to the handle of the chisel by the operator or his assistant. If this does not effect a separation, it is to be repeated. In forest pruning it is often advantageous to apply one cut of the chisel on the underside of the branch, and then saw it through with the forest-saw from the upper.

1888. Clipping is an imperfect mode of cutting adapted for expedition and for small shoots. The separation is effected by bruising or crushing along with cutting, and, in consequence, both sections are fractured. In gardening it is chiefly applied for keeping hedges and edgings in shape; but the hedge-knife (fig. 115.), which operates by clean, rapid, draw-cuts given always from below, is generally preferable, as not decreasing the live ends of the amputated shoots. The new pruning-shears (fig. 122.), and the avernumator (fig. 121.), it is to be observed, by producing cuts much more like the draw-cuts of knives, are greatly to be preferred to the common hedge-shears.

1889. In respect to the seasons for sawing, cutting, or clipping living trees, the best seem early in spring, and in midsummer. Early in autumn, trees are apt to bleed; later, and in winter, the section is liable to injury from the weather; but trees pruned early in spring remain only a short period before the wound begins to heal; and in those pruned at midsummer wounds heal immediately. There are, however, exceptions as to spring pruning in evergreens, cherries and other gummiferous trees; and summer pruning is but ill adapted for forest-work or trees in crowned scenery.

1890. Splitting, as an operation of gardening, is generally performed on roots of trees remaining in the soil, for the purpose of facilitating their eradication. The wedge in its simplest form, and of iron, is driven in by a hammer or mallet, till it produces fracture and separation, when the parts are removed as detached, &c.

1891. Mowing is performed by the rapid motion of a very sharp wedge across the matters to be cut or mown, and at an oblique angle to them. In gardening it is applied to grassy surfaces, in order, by repeated amputations, to keep the plants short, spreading, and thick, and by always admitting light and air to the roots or stools, to render the surface green. This operation requiring great force, and also a twisting motion of the body, brings almost every muscle into action, and is, in fact, one of the most severe in vegetable culture.

1892. Mowing from a boat, is in use for cutting weeds in rivers and ponds. The operator stands in the boat, and is rowed forward by another, as required. Sometimes scythe-blades are tied or rivetted together, and worked by means of ropes like a saw from one shore to the other; but the first mode is generally reckoned the best, even in public canals, and is unquestionably so in gardening.

1893. Weeding is the operation of drawing or digging out such plants from any given
plot as are foreign to those cultivated there. In this sense every plant may become a weed relatively; but absolute or universal weeds are such as are cultivated in no department of gardening, excepting in that purely botanical. Weeds are drawn out of the ground by the hand or by pincers (fig. 146.), or they are dug or forked out by weeding tools. Aquatic weeds are necessarily drawn up by pincers. The best season for weeding is after rain.

Chapter II.

Operations of Gardening in which Skill is more required than Strength.

1894. Operations of skill require the end to be known and kept in view by the operator, during the operation. The labors which we have enumerated in the foregoing chapter, may almost all be performed by the laborer without reference to any plan or design; but those which come next to be enumerated, require a greater or lesser degree of reference to the ultimate object. Of this, even the simple operations of digging a drain to carry off water, planting in a row, or forming a bed of earth, may be mentioned as examples. Previously to proceeding to these operations, it becomes necessary to consider the subject of transferring designs from ground to paper, or to memory, and from paper or memory to ground; we shall then be prepared to treat of executing designs.

Section I. Of transferring Designs from Ground to Paper or Memory.

1895. The subject of taking plans or designs of objects is to be considered as part of a gardener’s general education, since none who aspire to any degree of eminence in their art ought to be ignorant of the first principles of geometry, land-surveying, and drawing. We shall merely, therefore, touch on a few points with a view to assisting a gardener in bringing the knowledge he has so acquired into action. A gardener may require to take plans of gardens, or parts of gardens, or of implements or buildings, for his own instruction, or to execute similar objects for his employer. It is as requisite, therefore, that a gardener should be able to copy a garden, as a carpenter a gate or a roof.

1896. The dimensions of simple objects, as of a bed of earth or dung, border or other plot, he may retain in memory, and transfer from memory to the imitation or copy; but in general he will require the assistance of graphic memorandums, either of the pen or pencil, or both. The instruments necessary for taking measurements and angles so as to transfer plants from the ground to paper, are the measuring-line or chain, the measuring-rod, and occasionally the theodolite; but for all ordinary purposes the chain and rod are sufficient.

1897. The simplest form of surface-plan to transfer from ground to paper is a circle; for here it is only necessary to find the diameter. The next is a parallelogram or bed, in which it is only requisite to take the length and breadth. Most of the details of the plans of kitchen-gardens, may be reduced to parallelograms, so that they are transferred to paper, or even taken down arithmetically, as in the land-surveyor’s field-book, with great ease.

1898. Irregular figures, as parterres, outlines of picturesque plantations (fig. 348.), or water; or the plans of winding walks, require greater nicety. In such cases, temporary or imaginary lines (fig. 348. a, b, c), forming parts of regular figures (as d with b, fig. 348.) are first to be formed, or partially indicated around, or through the plot to be transferred; and dimensions are next to be taken relatively to these known and simple lines or figures. Of all temporary or skeleton figures, the triangle is the most simple, the most correct, and the most generally used. The skeleton or temporary figure (e) or line (a b, &c.) being transferred to paper, the dimensions (d) are set off from it, and the irregular plot and all its details are thus correctly protracted.

1899. Raised or depressed surfaces, whether naturally or artificially so, require a sort of double measurement; first, horizontally, by true horizontal lines, to get the surface-plan; and next, to measure their elevations or depressions from these lines, in order to find their height or depth. Few gardens of any description are made perfectly flat; the borders of
the kitchen-departments generally rise on each side of the walks; and in large parterres, one of the chief beauties arises from the inequalities of the surface. The depth of ponds, excavations for dung, earth, &c. ridges, hot-beds, rockworks, even houses, trees, &c. are all to be measured with reference both to their horizontal and perpendicular extensions. Four persons are required in performing such operations accurately; two to hold the chain or line in a horizontal position, or in the plane of the general surface; one to take the dimensions downwards or upwards from this with the measuring-rod, and one to mark down the dimensions.

1900. In protracting elevations and depressions on paper, the simplest way is to introduce sections, in dotted or otherwise distinguished lines, to prevent their being mistaken for surface-lines; or in wavy surfaces, figures may be introduced, thus \( \pi \) or \( \tau \), to denote their elevation above, or depression below, some piece of water, or other surface fixed on as a medium. Some excellent observations on this subject will be found in Major Lehman's Topographical Plan Drawing, as translated by Lieutenant Siborn, (oblong f. Lond. 1829,) which it is to be hoped will soon be appropriated in the popular books on landsurveying, and adopted in practice.

1901. Where it is in contemplation to form pieces of water, the elevations and depressions or levels must be taken and recorded either by sections or arithmetically with the greatest accuracy; and, in some cases, sections may require to be taken to show particular trees, buildings, the depth of water, or other objects. (fig. 349.)

1902. With respect to the elevations and shapes of hills and mountains which may lie within parks or plantations, they are only to be measured correctly by the quadrant and theodolite, in the hands of regular land-surveyors; and, therefore, are not considered as here included. Their shape and dimensions are laid down in maps in the same manner as those of smaller deviations from the flat surface. Inaccessible dimensions of height, as of trees or buildings, are obtained by the quadrant, or by relative comparisons of shadows; of depth, as of water or wells, by rods; of breadth or length, by finding the two angles of a triangle whose base shall be in one extremity of the distance; and apex in the other. These, and many other equally simple problems in trigonometry, need not be enlarged on, because they must be supposed to form a part of general education.

1903. The greatest accuracy is requisite in transferring plans of garden-scenery. Not only the mere ground-lines are to be transferred; but to form a complete plan, the distances between scattered trees or trees in rows, or otherwise regularly disposed, ought to be marked, the situations of their stems indicated, and, where they are of considerable size, representations of the horizontal extension of their heads (fig. 350. b) should also be given. The same ought to be done in the case of walls, buildings, and all other raised objects. The intention of a ground-plan is to give an idea of the superstructure; and without such additions as these and others of a pictorial nature (fig. 350.), to the mere ground-lines, that idea must be very imperfect, at least in plans of mixed scenery.

1904. For protracting rural objects various modes have been adopted by land-surveyors; trees are sometimes shown by small crosses or ciphers, triangles or dots (fig. 350. a); by

an orbiculate line representing the extension of the branches or head, and a dot in the place of the trunk (a and c); by the same, with the addition of a shadow, taken when the sun is south or south-west, and his elevation exactly 45°, by which the points of the compass are readily ascertained throughout the plan, and the shape of the head, and the height of the tree exhibited (c); sometimes an elevation or profile of the tree is given, either
in foliage (f), or to show the form of the trunk and branches (g), or merely to give a rude idea of a tree (c). Hedge-rows, whether with or without trees, are either shown in elevation or profile (h), or in vertical profile or bird's-eye view (i). They may be delineated either in skeleton or foliage. Buildings may be shown either in general plan (k), detailed plan (l), vertical profile of the roof (m), elevation (n), perspective view (o); or a plan may be given (p), and a diagonal elevation (q) taken and placed opposite the plan in the margin of the map. A pictorial surveyor, who understands perspective, and is desirous of conveying a correct idea of the subject he is to measure and delineate, will readily find expediency for attaining success.

1905. In portraying the general surface of land-estates, different modes have been adopted by modern land-surveyors. The first we shall mention is the old mode of giving what may be called the ground-lines only; as of roads, fences, water-courses, situations of buildings and trees. (fig. 351.) This mode has no other pretensions than that of accuracy of dimensions, and can give few ideas to a stranger who has not seen the property, beside those of its contents and general outline.

1906. In the second, elevations of the objects are added to these lines; but which, in crowded parts, tend much to obscure them. (fig. 352.) This mode is perhaps the best calculated of any to give common observers a general notion of an estate; more especially if ably executed. Very frequently, however, this mode is attempted by artists ignorant of the first principles of drawing, optics, or perspective, and without taste.

1907. In the third, a vertical profile, or geometrical bird's-eye view, that is, a bird's-eye view in which all the objects are laid down to a scale is presented. In this the upper surface of every object is seen exactly as it would appear to an eye considerably elevated above it, and looking centrically down on it. (fig. 353.) This mode, properly executed,
is calculated to give a more accurate idea of the furniture or surface-objects of an estate than any other; and if the declivities be correctly indicated, and the shade of the hollows and eminences be laid on with reference to some medium elevation, referred to or illustrated by sections, taken in the direction of indicated lines (a...b), it will give an equally correct idea of the variations of the ground. In short, it is the best mode for most purposes, and is now coming into general use.

1908. A very complete method of giving the plan of an estate, is to adopt the profile manner and include such a portion of the plans of the adjoining estates or country as shall be contained within a circle of moderate extent (fig. 354.), the centre of which may be the centre of the demesne-lands, family-mansion, or prospect-tower. Around a map so formed, the distant scenery, as seen from the roof of the house or prospect-tower, may form a panoramic circumference, or margin of prospects. (fig. 354.) In all these modes, dimensions and contents are given or obtainable along with effect; in those which follow, effect or general appearance only is obtained.

1909. The natural bird's-eye view is intended to give a general idea of the external appearance of an estate. In this the eye of the spectator is supposed to be considerably elevated above the centre of the estate, and all the objects are portrayed exactly as they would appear to him in that situation; largest in the centre, and gradually diminishing to the circumference of the circle of vision. In such a delineation, parts of other adjoining estates may often require to be included, in order to complete the circle; but these are necessary to the general idea, and can easily be distinguished from the principal property by minute marks on the delineation.

1910. In the panoramic view, the delineator supposes himself placed on an eminence, as the roof of the mansion, where centrical, and looking round on all that he sees on every side. Where there is a prominent hill, or where the mansion is on an eminence, this is a very desirable mode of giving a general idea of a domain, and by the aid of horizontal lines and lines converging to them from the centre of vision, some idea may be had, on flat surfaces at least, of the relative heights and distances of objects.

1911. A simple mode is to give a general view, or distant prospect of the estate, or its
principal parts (fig. 355.), as seen from some elevated conspicuous hill, building, or object near it; or if the estate, as is frequently the case, is situated on the side of a hill, or range of hills, a situation on the plain, or flat grounds opposite to it, will be sufficient.

1912. Great improvements have been made in the art of delineating estates by T. Hornor, an elegant and scientific chorometer and draughtsman. See his Mode of Delineating Estates, 8vo. 1813; and Lehman’s Topographical Plan Drawing, oblong fol. 1822. Models of estates are also formed in cork, papier machée, and other substances, which for hilly scenery are very useful and entertaining.

Sect. II. Of transferring Designs from Paper or Memory to Ground.

1913. Staking or marking out plane is a subject requiring much greater skill than the last, on account of the inequalities and other obstructions met with on the ground’s surface. It may be considered, 1. As to transferring figures to plane surfaces; 2. To irregular or obstructed surfaces; and, 3. Arranging quantities.

Subsect. 1. Transferring Figures and Designs to plane Surfaces.

1914. The transferring of plane or regular figures to even ground is nothing more than performing the elementary problems of geometry on a large scale. The subject has been amply illustrated by Switzer, Le Blond, and other writers of their day; but a very few examples will here suffice, as the school education of gardeners is now superior to what it was in those times.

1915. A perpendicular to any line may either be found by taking a garden-line, doubling a portion of it, and applying the extremities at equal distances from the point whence the perpendicular is to proceed (fig. 356. a); or more simply, but on a large scale with less accuracy, by applying the garden-square (b), or on any scale by the use of a rope or line united at the extremity, and divided in the proportions of 6, 8, and 10 (c). The 6 is to be placed as the perpendicular of a right-angled triangle, the 8 as the base, and the 10 as the hypotenuse; or three rods of similar proportions, or divided into feet, and the proper numbers taken, may be used for this purpose. Switzer informs us this was the mode in which all right-angled figures in gardens, and all other works, were set out in his time.

1916. To divide an angle, a line united at the extremities, and divided into four equal parts (d), may readily be so applied to any angle as to divide it equally; or the same thing may be done by a portion of line bisected, and its extremities applied at equal distances from the angle (e). A line divided into three equal parts readily forms an equilateral triangle (fig. 356. f).

1917. To describe an oval within a given length, the length may be divided into three equal parts; then let the two inner points so found be the centres of two circles which shall form the ends of the oval, and the sides may be formed by segments whose centres are the intersecting points of the circles (fig. 357. a). The same oval may be formed by
dividing the given line into four parts; forming the ends by segments of which the two outermost points are the centres, and the sides by segments proceeding from a line passing at right angles through the centre of the given line (fig. 357. b).

1918. The gardener’s oval, or one in which both diameters are given, is thus formed. Bisect the long diameter by the transverse one, itself thus bisected by the other. Divide half the transverse diameter into three parts. Take one of these parts, and set it off from both extremities of the long diameter. Fix there two pins or stakes, and fix a third stake one part from the end of the transverse diameter; double a line and put it round these stakes, of such a length that when stretched, it may touch the extremities of one of the diameters. Then, with a pin in this extremity, move it completely round, and so strike out the oval (fig. 357. c). The long and short diameters are more easily divided arithmetically; thus, supposing the given length of the oval be ninety feet, and its width sixty feet; then the third part of half of the width is ten feet, and this distance set back from the extremities of the diameters gives the situation of the stakes at once.

1919. A spiral line, or volute, may be sometimes required in gardening, for laying out labyrinths or curious parterres. The width or diameter of the spiral being given (fig. 358. l, h), bisect it, and divide each half into as many parts as the spiral is to form revolutions (fig. 358. g to h). Then, from the centre draw all the halves of the spirals which are on one side of the diameter line (bc, dc, fg, hi); and from the point where the first semispiral intersects the diameter line (b), as a centre, draw all the others (dc, fe, hg).

1920. Uniting three points in a curved line. A very useful problem both in laying down plans on paper, and transferring them to gardening, is that which teaches how, from any three points (fig. 359. a, b, c), not in a straight line, to find the centre of a circle whose circumference shall pass through them. Imagine the three points connected by two straight lines; bisect these lines by others (g and e), perpendicular to them, and where these intersect (at g) will be found the centre of the circle whose circumference shall pass through the three points.

1921. The method of laying out polygons on even ground, or any geometrical figure, will be perfectly simple to such as can perform the problems on paper; all the difference on the ground is, that the line is used instead of the compasses, with or without the assistance of the square and arithmetical calculation.

1922. Laying out the ground-lines of gardens, parterres, or any large figures on plain surfaces, is merely a mixed application of geometrical problems. It is only necessary to premise, that a straight line is found by placing rods upright, so as they may range one behind the other at convenient distances, and so accurately adjusted, that the one next the eye may conceal all the rest. A plan of a garden, &c. (fig. 360. a) being given with a scale and north and south line attached, first find its extreme dimensions, and supposing you have space sufficient for laying it out, find the central lines (fig. 361. a, a, b, b), and lay them down first, distinguishing them by rows of stakes; then from these set off the lines of the central plot, if any, the walks, alleys, walls, &c., distinguishing them by strong stakes, which may remain till the ground is put into proper form.

1923. In laying out polygonal gardens, or plots, or ponds (fig. 360. b), when the dimen-
sions are too great for inscribing a circle of the full size with a line; the obvious mode is to form a small circle in the centre, and mark the figure on its circumference; then from the points where the sides intersect radii can be extended as far as required, and the length of one being found, the rest can be adjusted accordingly, and the plot thus laid out of the required size. (fig. 362.)

1924. Intricate and fanciful figures of parterres are most correctly transferred to ground, as they are copied on paper, by covering the figure to be copied with squares (fig. 363. a) formed by temporary lines intersecting each other at equal distances and right angles, and by tracing on the ground similar squares, but much larger, according to the scale (fig. 363. b). Sometimes the figure is drawn on paper in black, and the squares in red, while the squares on the ground are formed as sawyers mark the intended path of the saw before sawing up a log of timber; that is, by stretching cords rubbed with chalk, which, by being struck on the ground (previously made perfectly smooth), leave white lines. With the plan in one hand and a pointed rod in the other, the design is thus readily traced across these indications. The French and Italians lay out their most curious parterres (fig. 364.) in this way.

Subsect. 2. Transferring Figures and Designs to irregular Surfaces.

1925. Staking or marking out plans on irregular surfaces constitutes the most difficult part of practice, whether in arranging grounds in the country, or streets, or other improvements in towns. These difficulties do not arise from the intricacy of the principles of action; but from the variety of operations often requisite to overcome the obstruc-
1926. Where a straight line is to be indicated among objects or inequalities not more than fifteen or twenty feet high, its plan or tract on the earth (fig. 365. a \ldots b) may be found by the use of poles, a few feet higher than the elevation of the obstructions, the director being placed on a step-ladder, or other elevation at one end. Where this method cannot be adopted on account of the height of the inequalities, the line must either be formed along the summits of these inequalities, which may be done if they are houses, hills, or trees; or parallel lines (c, d, e) formed where practicable, and the main line found by offsets (f, g, h) from those collateral lines at such places as are suitable. A third method, but one not always perfectly accurate, is to take a plan of the field or scene of operations, and on this to set out the proposed line; then by ascertaining its bearings and distances relatively to the obstructions, it may be transferred from the paper to the ground. In carrying straight lines through woods, lanterns have been used; but a much more correct method is to elevate poles above the surface of the wood.

1927. Continuous lines may always be made perfectly straight, however irregular the surface, by following the same parallel as indicated by points of the compass; or by the shadow of the operator during sunshine. If the needle does not move, or the shadow of the spectator is always projected at the same angle to his course, the direction in which he walks, in either case, must be straight. The mode of forming right lines in such circumstances being understood, the formation of right-lined figures is merely a repetition of the process, uniting each side by the required angle.

1928. Curved lines on irregular surfaces are in general only to be laid down by the previous establishment of straight lines; first, leading straight lines (fig. 348. a, b, c) and next secondary straight lines (fig. 348. d, d), which shall form skeletons to the curves. A second method, and on a large scale by much the most certain, is to find the leading points of the curves by triangles from a known base or known bases; but as both modes are rare in the practice of gardening, they need not be enlarged on.

1929. Circles, ovals, and every description of curvilinear figure may be laid down by either of the above modes; but where the obstructions are not great, circles, or parts of circles, may be transferred more expeditiously by the following method. The diameter of the circle (fig. 366.2), and any two points (a and c) which its circumference is to touch, being given, next ascertain the side of the largest square which the circle will contain. Then, if the director place himself in the given point of the circumference, and look either through the sights of a theodolite, or along the edge of a common carpenter's square (d), or any right-angled board, the straight line traced by his eye will intersect the situation of the circumference of the circle; if he then causes to be measured along that straight line, the length of the side of the square contained within the circle, the extent of the dimension will determine a point in the circumference. Then looking along the other side of the square, or through the sights of the theodolite at right angles to the former observation, he will by a similar process determine another circumferential point; and now, by changing his position either to the right or left, taking care to set off always the same dimension from the side of the square, he will trace out the circumference of the circle or any portion of it. It is evident to any person in the slightest degree acquainted with
practical geometry, that the same object may be attained by an adjusted triangle (such as e), the extremities of which will indicate points in the circumference without further trouble.

1930. Other modes on similar principles, well known to land-surveyors, are occasionally resorted to in laying out gardens, especially in the geometric style, and in preparing the foundations of farmeries, and other rural offices and appendages. A very obvious application of it is that of reducing an irregular basin of water to a circular figure. The director moves round with the adjusted triangle (fig. 367, a); his assistant sets off the dimensions and as each point in the circumference is ascertained, it is marked by a stake (b, c, d).

1931. A level line (fig. 368, f, f), whether straight or curved in direction, can only be determined on an irregular surface by measuring down from an elevated level line (a), or from level lines in parallel directions, and so transferring the points by horizontal levels to the proper line. Straight rods are the ready means of measuring down, and the points must be marked by hillocks or hollows (b); or by smooth-headed stakes driven into the surface, and protruding above, or sunk under it, according to the obstructions.

1932. Lines of uniform acclivity or declivity (fig. 368, e, c, e) are readily formed on the same principle. In this and the former case, the common level and the boring-pieces (a and d), with measuring rods and stakes, are all the instruments required. The formation of level lines and uniform slopes, by the boring-pieces and common level, ought to be familiar to every working-gardener; for, without considerable adroitness in this department of garden-operations, none can be considered as fit to form a walk, or even plant a box-edging.

1933. Levelling for terrace-slopes (fig. 369), or for geometrical surfaces, however varied, is performed by the union of both modes, and requires no explanation to those who have acquired the rudiments of geometry, or understand what has been described.

Subsect. 3. Of the Arrangement of Quantities.

1934. The dividing and subdividing of land is generally the business of the land-surveyor, but it sometimes comes under the practice of the gardener, on a small scale, and on simple principles. Thus it may be required to determine the dimensions of a square, of a circle, of an oval, or of a mixed figure of a kitchen-garden, which shall contain a certain
number of acres, or acres and parts of acres. Or, on a certain compartment in a garden of given breadth and length, it may be required to sow or plant a certain number of poles of any given crop, &c.

1935. Where the figures are simple and regular, as squares, parallelograms, triangles, circles, &c., these problems are easily solved; but where they are irregular, the safest way for practical gardeners, not much in the habit of calculation, is by trial and correction. Thus, supposing it required to find the dimensions and ground-plan of a garden-wall, which shall enclose two acres, the north and south walls to be straight and parallel, and the two ends parts of ellipses. Try a parallelogram, which shall contain \(\frac{1}{2}\) acres, and try and adjust two curves to its ends, which shall each contain \(\frac{1}{2}\) of an acre. If an eighth of an acre does not give sufficiently curved ends, narrow the parallelogram part a little, which will admit an increase to the curved ends. All this being laid down on paper to a scale, when the figure is completed, ascertain its contents by the scale, and vary it as above, till it corresponds exactly with what is required.

1936. For more intricate figures, first cover the paper with squares, each containing a certain area; say a yard, a pole, &c., according to the magnitude of the design to be adjusted. Then, on these squares adjust the form and the contents of the given figure, by alternate delineations of the desired shape, and numbering the squares for the desired contents. When the end appears to be attained, prove the whole by measuring from the scale.

1937. With respect to measuring for cropping compartments or borders, supposing it is desired to sow three poles of turnips on a compartment 60 feet broad, then the first question is simply, given 60 feet as one side, required the length of another requisite to form a pole. A pole contains \(30\frac{1}{2}\) square yards, or \(273\frac{1}{2}\) square feet; dividing the last sum by 60, the quotient, 4 feet \(6\frac{1}{2}\), is the length of one pole at this breadth. Or, if by links, then 60 feet = 136 \(\frac{2}{3}\) links, and 625 square links = 1 square pole; hence 625 = 136 \(\frac{2}{3}\) = 6 \(\frac{1}{2}\) links. 3 \(\times\) 4 feet \(6\frac{1}{2}\) inches, or \(3 \times 6\frac{1}{2}\) links = 13 feet 8 inches, or 20 \(\frac{1}{2}\) links, the length of three poles of the given breadth.

1938. For arranging work done by contract, it is necessary for the gardener to be able to determine the superficial and solid contents of ground, whether it is to be cultivated on the surface, as in digging or hoeing; turned over to a considerable depth, as in digging drains or trenching; or removed from its place, as in former excavation for water or foundations. All this is abundantly simple, where the first rudiments of mensuration are understood. The most important part is what relates to digging out large excavations, and wheeling the earth to different distances; and to guide in this, the following rules, known to every canal contractor, may be worth attending to by the gardener.

1939. For excavating and transporting earth. In soft ground, where no other tool than the spade is necessary, a man will throw up a cubic yard of 27 solid feet in an hour, or ten cubic yards in a day. But if picking or hacking be necessary, an additional man will be required; and very strong gravel will require two. The rates of a cubic yard, depending thus upon each circumstance, they will be in the ratio of the arithmetical numbers 1, 2, 3.

If, therefore, the wages of a laborer be \(2s.\ 6d.\) per day, the price of a yard will be \(3d.\) for cutting only, \(6d.\) for cutting and hacking, and \(9d.\) when two hackers are necessary. In sandy ground, when wheeling is requisite, three men will be required to remove 30 cubic yards in a day, to the distance of 20 yards, two filling and one wheeling; but to remove the same quantity in a day, to any greater distance, an additional man will be required for every twenty yards.

To find the price of removing any number of cubic yards to any given distance: Divide the diameter in yards by 20, which gives the number of wheels; add the two cutters to the quotient, and you will have the whole number employed; multiply the sum by the daily wages of a laborer, and the produce will be the price of 30 cubic yards. Then, as 20 cubic yards is to the whole number, so is the price of 30 cubic yards to the cost of the whole.

Example. What will it cost to remove 2730 cubic yards to the distance of 120 yards, a man’s wages being three shillings per day? First, \(120 \div 20 = 6\), the number of wheelers; then, + \(\frac{1}{2}\) fillers = 8 men employed, which, at three shillings per day, gives 24 shillings as the price of 30 cubic yards; then \(30 \times 24 = 720\) and \(34 \times 2730 \div 30 = 110\).

For elementary instructions in this department, see Hutton’s Mensuration, Nicholson’s Architectural Dictionary, and the article Canal, in the principal Encyclopedias.

Sect. III. Of carrying Designs into Execution.

1940. To realise alterations projected or marked out on the ground, recourse is had to the mechanical operations of gardening. These require to be directed to the following objects. Removing surface incumbrances, smoothing surfaces, draining off superfluous water, forming excavations for retaining water, forming artificial surfaces, and forming walks and roads.

1941. Removing surface incumbrances is one of the first operations of improvement in reclaiming neglected lands, or preparing them for ulterior purposes. The obstacles are generally large blocks of stone, bushes, roots of trees, and sometimes artificial obstacles, as parts of walls, hedges, buildings, &c. Where the stones cannot ultimately be ren-
CARRYING DESIGNS INTO EXECUTION.

1942. Smoothing surfaces. Whatever be the nature of the future improvements, this operation generally takes place to a certain extent after the removal of obstacles. Pits, quarries, pools, &c. are to be filled up; banks, dykes, artificial mounds, and excrescences to be broken down and scattered about, before the natural surface can be duly understood and appreciated, and before drains and other preliminary improvements, as roads, fences, &c., can be conveniently marked out.

1943. Drawing off superficial water by subterranean drains. The theory of this subject has been already noticed (1096.), and as it more properly belongs to agriculture than gardening, we shall confine our remarks to execution. The designer or director of the improvements, having, by the aid of levelling, and consideration of the causes of the superficial moisture, marked out by proper stakes the main drain and lateral cuts, the lowest point or outlet of the former is first to be begun on, and excavated to the proper width and depth. If the soil is very soft, the materials for filling in, or forming the channel, or drain, should have been previously carted there, as this operation, performed on soft ground after the excavation is made, is apt to damage the sides of the drain. No part of the drain ought to be filled, till the whole has been completed, and any errors in the level of its bottom or water-way corrected. The height to which the materials are to be laid, must be regulated by the use to which the surface is to be applied. For permanent pastures, as in lawns and parks, they may be brought near the surface, but in kitchen-gardens, or sceneries were digging or trenching are occasionally to take place, they should not come within six inches of the bottom of the loosened strata. As to materials for drains, whatever will form a porous or hollow stratum or vein may be employed; but round stones are unquestionably the most durable for collecting-drains; and tubes of earthenware, or built drains of stone or bricks, for drains of conveyance. The most complete description of master-drain, is one with a built cylinder or barrel of stone or brick below, covered by a vein or vertical stratum of round stones, terminating near the surface in coarse gravel. Wherever much draining is to be done, all the various methods should be considered as detailed in the county surveys, and collected in Marshall’s Treatise on Landed Property, and Johnston’s System of Draining; and those fixed on which may be considered as most suitable to the particular case.

1944. Forming excavations for retaining water. Previously to commencing this operation, the levels must be staked out with great accuracy, as well as the places indicated from which the larger masses of earth are to be moved or to which they are to be taken. Excavations for water vary in respect to the difficulties and manner of execution, according as they may be intended for running or stagnated water; for water already existing on the spot, or to be brought there, or according to the nature of the soil and surface. For running water more depends on the design than on the execution; for a current, if well directed, will, in a short time, form a suitable bed and banks for itself; but for stagnated water all depends on art, both in the design of the shape and the execution of the bed and margin. Water already existing in a body on the spot generally implies a suitableness of soil for retaining it, and the existence of springs for an increased supply, and these serve as useful guides in the course of execution: but where water is to be brought to a situation, it generally implies an unsuitableness both of soil and surface to retain it, and hence requires the greatest attention in the application of art, both as to design and execution. The most suitable surface for water is a hollow or level, and the best soil a clay or strong loam. In all these cases the executive part reduces itself to three oper-
ations; the removal and disposal of the earth, the formation of the bed and margin, and the formation of the dam or head and sluice.

1946. In the removal and disposal of the earth, regard should be had to preserve the best soil for what is to be future surface; and, in poor lands, it may often be advisable to dig or pare off the surface of the spots to be covered by the excavated earth, and preserve them for the same purpose. Where the new soil is to be thinly scattered over the old, fallowing, trenching, or digging may effect the proper mixture. When large masses of new earth are to be laid down, that of worse quality must be farthest removed from the probable reach of the roots of future trees; or, if the roots of trees will penetrate the whole mass, then the whole soil should be mixed. Gravelly materials should be kept at such a distance from the margin of the water, as not to act as a drain from it; and, in forming the mass of earth requisite at most dams or heads, the less gravel or porous matter used alone, the more compact and retentive will be the head. In every mode in which excavated earth is disposed of, care is requisite to blend its outlines with those already existing, so as to avoid all appearance of patches laid on, bumps, warts, or excrescences, than which nothing is more disagreeable in surfaces.

1947. In the formation of the bed, where the excavation has been made in a level surface, no farther attention is requisite than attending to the depths indicated in the design, which will generally be greatest towards the middle, and diminishing to the sides, as in nature. Few pieces of water require to be deeper in the middle than ten feet, which will generally deter cattle from wading across them, and prove unfavorable for the growth of most aquatic plants. Where water is formed by damming up, or throwing a head across a hollow, of which, perhaps, the most notable instance on record is that of Blenheim, the bottom does not require any attention, excepting adjoining the head; the mass of materials forming which should form an inclined plane under the body of water for the sake of securing the head; and to prevent the water from penetrating into this mass of materials, its surface should be regularly clayed or puddled over, as well as a part of the firm ground on all sides, and even in the bottom of the excavation. For if this firm ground is of a sandy or gravelly nature, the water may, by entering it, find its way to the mass of new and not yet consolidated earthy matters, and by softening them, speedily ruin the whole mound or head. A safe mode is to leave the head to consolidate for a year or more before filling with water. This was Brown's practice at Blenheim, Harewood Hall, and other places.

1948. When water is formed on the side of a hill, the lower part of the excavation must be raised and clayed with equal care, as in the case of the head or dam, and for the same reasons. It is almost needless to mention, that claying must never be omitted where the bottom or sides are either newly formed, or not naturally retentive of water. Where clay cannot be had, loamy, or calcareous, and even somewhat sandy earth, by abundant working, becomes retentive of water. This the celebrated engineer Brindley first discovered and practised.

1949. The margin of all water, where nature is imitated, ought, as much as possible, to be formed of stony or gravelly materials, as most likely to give a dry appearance quite to the edge of the water, to admit of walking there, of cattle drinking without poaching and bemoaning themselves, and to prevent the growth of such grasses and aquatics as communicate a morass or marshy appearance; and finally as being more natural and picturesque than banks of mud. For this purpose, during the excavation, all or a suitable quantity of such gravelly or stony materials as occur, should be reserved for depositing along the margin, for at least one yard beyond the edge of the water, and two yards down the slope of the bed. If suitable materials are not to be had from the excavation, they should be procured; for without them there can be but little beauty in the margins at least of stagnated water. The margins of rivers may be left in a great degree to nature, watching every proper opportunity after floods or winds, to heighten indications of picturesque effects, not materially inconsistent with local character and utility.

1950. In the formation of the head, or dam (fig. 370. d), the points requiring particular attention are the claying, and the forming the sluice or valve for emptying the pond. Claying should either be performed over the whole of the inner surface of the head, or by a perpendicular stratum of clay in the middle of the bank.
The last mode is the most simple of execution; but if the great body of loose materials are of a sandy or porous nature, the former will be found the safest; either however, well executed, will suffice; and in this point of practice, execution is certainly of more consequence than design.

1951. The sluice is the stopper or valve to a drain (fig. 370. c), carried through the bank of a piece of artificial water at the lowest part of its bed, in order to be able to empty it at pleasure. There are various kinds, from the simple tube and stopper (fig. 371. a), to the plank-sluice (c), or grooved frame (b). This last is formed of a plate of boards, generally two or three feet wide, and six or eight feet high, attached to a stalk, and worked by means of a pinion and rachet in a frame of timber. The sluice is built vertically into the drain as a damper is into a flue, and the length of the stalk and frame is always such as to reach somewhat above the ground's surface for convenience of working. The grand object as to the sluice is to construct it so as to admit the least possible escape of water. This will generally be best attained by forming the tunnel, in which the sluice is to be built, in the solid ground at the side of the head, and not in the new and loose earth, building it of masonry or brick set in cement, claying it completely on all sides, and fitting in the sluice with the greatest nicety.

1952. Syphon sluice. As it is practically impossible to form sluices and drains that do not lose more or less water, owing to the great pressure of the volume in the lake or pond, it is better, where the supply is very limited, to have no drain or sluice, and to draw off the water when required by a large syphon, which may easily be formed of boards; or a drain may be formed, and, instead of a sluice, a well of clay adopted as a stopper. The power of drawing off the water is seldom used, and, unless in fishponds, or where frequent clearing is necessary, sluices are of little use. The superfluous water which escapes over the head when abundant, may form a cascade or waterfall; but where the waste is small, it may escape at one side (fig. 371. a) as a small gurgling rill over a bed formed of well-worked clay, to prevent its working out hollows, and covered by gravel, stones, &c., to give it a clear and natural-like appearance. As the head is generally a straight mound, destitute of natural beauty, it should be disguised by small islands (fig. 372. b, c), or varied by planting on the margin, or both; but as our present business is merely to describe the operations requisite to the formation of pieces of water, we must refer, for what concerns it as a material of landscape, to Landscape-gardening. (Part III. Book IV.)

1953. Surfaces to imitate nature, such as hills, knolls, and all the variety of raised surfaces in pleasure-grounds, are formed by heaping up materials in the indicated shapes; and hollows of equal variety, by hollowing them out; in both cases, studying to keep the best earth at the surface, and so to blend the forms with those to which they are united, that no line of demarcation may ever afterwards be discoverable.

1954. Surfaces newly artificial, as levels, terraces, slopes, banks, beds of earth, or dung-beds, being once distinctly marked out, are executed with equal facility and greater certainty of attaining the end or effect. Formerly the geometric style of gardening afforded an ample field for the exercise of this class of operations; but at present they are chiefly confined to the kitchen-garden, the sites of buildings, and a limited space around
the mansion. Whatever may be the surface destined for a court or square of buildings, as a stable-yard or farmery, it must be reduced to a plane or planes connected in such a way as not to interfere with utility or effect. It is not essential that the surface be formed to a perfect level, or to any one slope, but that order and connection should enter into the choice of the slopes, whatever that may be. In kitchen-gardens it sometimes happens that a level, or one general slope, may be adopted; but much more frequently that different slopes enter into the composition of the enclosed surface. These subordinate planes or surfaces are all so connected as to balance and harmonise, and present to the intelligent eye a work, not of chance, but of design and reflection. In a seemingly level garden it often happens that not one of the compartments is level; but each compartment of itself forms one plane, diverging from the centre, north wall, or some other point of the garden, and terminating on the same level, at the extreme corners of the compartment, or at the lower extremity of the garden. Besides these means, the formation of raised borders, and the furniture of gardens, such as espaliers, bushes, &c. enable the designer to harmonise forms and surfaces seemingly the most incongruous and unsuitable for a scene of culture.

1955. There are two modes of reducing an irregular surface to one plane. The first is by taking sections of the surface in parallel lines at every ten or twenty feet distance, according as the surface may be more or less irregular; laying down these sections on paper geometrically, and from the whole finding a mean section. The stakes of all the parallel lines of levels still remaining in the ground, it will be easy to transfer the mean section by raising these stakes in some places, and lowering them in others, as the scale of the diagram will direct. The second and more general mode is by approximation, or trial and correction, which, in all ordinary cases, is sufficiently correct. Suppose an irregular surface, 100 feet square, is to be reduced to a level or plane. The degree of slope is first ascertained (by the American or any other level) from the highest side of the square to the lower, and it is found, we shall suppose, that the ground will not easily reduce to a horizontal surface. It is, therefore, determined to reduce it to a slope; and for this purpose a certain height is determined on by the eye for the extremities of the slope; in fixing on which, the object is to adjust the slope to the earth, so as the former may be completed without exterior aid or superfluity. Supposing the lower side of the plot to be twenty-five inches below the level of the upper side, then the fall is a quarter of an inch in each foot, and a few lines of stakes can be run across the ground in the direction of the slope, with their tops adjusted to this declivity. Or this may be omitted, and the same end attained by boring-pieces used after the ground has been roughly levelled. But this is one, among many parts of the business of a gardener, which can more readily be acquired by practice than verbal instruction.

1956. Walks are spaces in gardens formed for the purposes of inspecting the garden, recreation, and carrying on the operations of gardening. As one great requisite is, that they should always be dry, the bottom of the walk in most cases forms a drain. There are three descriptions of walks common to gardens, those of gravel, sand, and grass. All walks consist of two parts, their substrata and surface-covering. The substratum is generally placed in an excavation, the section of which is a segment of a circle, or an inverted pointed arch, being deepest in the centre, where, in wet soils and situations, a notch or drain is often formed to carry off the water which oozes from the sides of the bottom, or sinks through the gravel. In all ordinary cases, however, the water will run off without this notch, provided the general levels of the bottoms of the walks or the drains which cross them, or lead from them, be contrived accordingly. The foundation of the walks is to be filled with stones, the largest at bottom; or with rubbish of old buildings, flints, or any other similar materials, observing always to place the smallest at top. When this is done, before the covering of gravel, sand, or turf is laid on, the substratum should be well rolled, so as it may never afterwards vary its position, either with the weight of the covering, or any weight which may pass over it.

1957. The covering of gravel (fig. 373. a) need seldom be thicker than six inches, and generally four inches will be sufficient. That this gravel may bind in so thin a stratum, it is requisite that it be free from larger stones than those the size of a pigeon's egg, that the general size be that of large gooseberries or plums, and that there be about a sixth part of rusty sandy matter to promote its binding. The choice of gravel is seldom within the power of the gardener; but, in general, pit-gravel is to be preferred to river-gravel, as binding better, and having a better color. Gravel abounding in oxide of iron, if laid down where it is finally to remain, when newly taken out of the pit, and well watered and rolled, will often bind into one compact body like what is called puddling-stone. Such gravels, however,
are seldom well colored. The best in this respect in England, and also a good gravel for binding, is the gravel of Kensington, to which good qualities it adds of being the most beautiful in the world. There are some very agreeable sea-gravels, formed chiefly of small shells, or fragments of larger ones. The way to make a handsome walk with this gravel is to mix it with about a tenth part of a composition consisting of equal parts of brickdust and puzolana earth or Roman cement. This done, and the gravel laid down in a wet state, and well rolled, it will form a surface like that of shell-marble.

1958. Where a covering of sand is adopted, its thickness must depend on its qualities, and whether sand is taken from preference or necessity. When sand is taken from preference, the intention is to produce soft walks, which shall yield to the feet like turf, in which case its thickness may be from three to six inches; but if sand is used because gravel cannot be procured, then little more should be laid on than what is sufficient to fill up the interstices of the upper surface of the substrata. Sometimes an attempt is made to bind such sand, by mixing it with dried clay in a state of powder, or with the scrapings of stone roads, and then watering and rolling; but it is not often that this succeeds; and it may certainly be considered as unfortunate where the best walks about a residence are covered with sand.

1959. The covering of turf and earth (fig. 373. b) should not be less than six inches in thickness, that there may be sufficient pasturage and moisture for the roots of the grasses in the dry season. For this purpose, the soil laid under the turf should be a medium between a stiff clayey and a loose sandy soil, so as more completely to serve as a sponge than either.

1960. Substitutes for gravel and sand are burned lumps of clay reduced to powder, pounded bricks, stones, or slates, scoria, ashes, soaper's waste, coal, shells, sawdust, tanner's bark, ferruginous earth, and even moss or peat-earth. Bark and peat-earth are often used in Holland; the former, when fresh, has much of the color of Kensington gravel, and assorts well with vegetation.

1961. Substitutes for turf are green mosses recently gathered and stuck on mortar or cement; the same process with fihens from trees, or with flow-moss or heath-tops.

1962. The form of the surface of gravel, sand, and grass walks, should almost always be flat; or, in the case of gravel, gently raised in the middle, so as to throw the water towards the sides, in approaching which it may sink gently into the substrata. But in turf walks this should never be attempted; as it is desirable, on account of equally watering the plants, and retaining an equal firmness throughout their surface, that the water should sink in where it falls. It is a common practice to form turf walks of solid earth, without any regard to the substrata; and this succeeds very well in dry soils, and where such walks are little used, excepting in summer; but whenever turf walks are to be in constant use, the above is much the best way of forming them. Gravel and sand have, in like manner, been laid on the surface of the soil in small gardens, and in very dry sub-soils, and where this can be done with the attainment of the desired objects, it has this advantage, that the roots of trees may range under the walks, as indeed always happens in shrubberies and plantations. The scoria of metals, coal-ashes, the refuse of mines and glass-works, and other similar matters, are often used instead of gravel; but their color seldom harmonises well with that of vegetation.

1963. The breadth of walks generally depends on the extent or scale of the whole residence, and not of the particular garden or scene, which may be small, and yet connected with greater. They should never be narrower than is sufficient to allow a party of two to walk abreast, the minimum breadth for which is four feet six inches; but they may be large enough for a party of half a dozen, or in public walks, or walks in extensive pleasure-grounds, avenues, &c., for one or two dozen. For the latter number thirty-six feet suffices. The direction of walks depends on their particular use, and connection with the different scenes or subjects of gardening.

1964. Alleys are smaller walks generally covered with a thin coat of sand, gravel, or shells. In parterres they are sometimes of various widths, to suit the particular forms which constitute the design; and there also they are sometimes covered with different sorts of gravels, shells, scoriae, &c., or paved with flints, pebbles, &c.; but the alleys of separation, in walled gardens, are generally two feet wide, and formed in right lines, parallel to the main walks, or borders. Sometimes they are not gravelled, and at other times they are covered with road- grit, or the scrapings of roads; which, of course, is to be considered as the powder of the material of which the road is made, mixed with vegetable matter from the droppings of horses and cattle, and is considered as well adapted for binding or forming a compact surface.

1965. Roads are walks on a large scale; they are formed on the same general plan; but when of fifteen or twenty feet in breadth, and on a wet or retentive soil, they have generally a drain on each side instead of one in the centre. On the sides of slopes, where, during heavy rains, these roads intercept the water from the upper grounds, they should have frequent gratings, or pierced stones, communicating with the drains on
the upper side (fig. 374.), unless provision is made for intercepting the water before it comes on the gravel, by a gentle hollow (a), running parallel and close to the road, and communicating in like manner with the drains.

1966. The durability and comfort of roads and walks depend on their power to resist the action of animals walking on them, of machines being rolled over them, of weather, and of vegetation. A dry firm substratum is necessary for all these purposes; and this, as already observed, is to be obtained by draining either in the centre or in the sides, and by a stratum of gravel or fragments of stones; the largest, in walks, of two or three ounces each, and in garden-roads, of six or eight ounces; in both cases covered with smaller gravel. For resisting animals, a degree of compactness, solidity, and homogeneous texture of surface is requisite, according to the weight of the animals and their burdens, and the area of their feet. Thus, supposing a man to weigh seven hundred weight, and to carry a load of two hundred weight, and the area of one of his feet to be twenty-five inches, then the walk or road will require to bear at least forty pounds per square inch, and so on. But an animal not only presses vertically on a walk or road, but his feet (the feet of man singly, and of quadrupeds relatively to each other), acting as levers of the third kind, have a tendency to force up and derange the materials under the point of the foot in the action of walking, in the same way as the lower end of a ladder, when rearing up against a wall, has a tendency to press into and derange that part of the ground which acts as a fulcrum. Hence an additional reason for firmness of surface, and also for using small materials; for if the end of a ladder, or the extremity of the foot, or any point of pressure, were to exert itself on one end or extremity of a stone, it would act as a weight on the end of a lever; and, depressing one end and raising the other end, would derange at once the substratum and the surface. During rain, or when the surface of the road was moist, this operation would go on in at least a duplicate ratio. Whatever may be the weight of a four-wheeled carriage or waggon, it presses on the road on four points only, whose united areas seldom exceed one foot; hence the necessity of firmness, and also of materials reduced to a size, whose areas are less than the separate areas of the four pressing points, in order to prevent derangement from leverage or compound action. This subject has been ably illustrated by R. L. Edgeworth, and practically exemplified, to a great and beneficial extent, by J. L. M'Adam (Rules for repairing Roads, &c. 1823), and bids fair to effect an entire change in the system of public road-making followed in this country. (See our Encyc. of Agriculture.)

1967. To resist weather, the grand object is to get rid of superfluous water; subterraneous sources are to be cut off by drains, and surface water is not to be allowed to sink into the road, but the surface gently raised, and rendered and kept, by rolling and continually obliterating foot or machine marks, so smooth and impervious, as to throw the water entirely to the sides. By this means, the effects of frost, heavy carriages, and narrow wheels, is greatly lessened.

1968. To resist vegetation, a road must be in constant use; but firmness is useful even in this point of view, and also the exclusion of vegetable earths from the gravels or other materials used in forming the surface of garden-walks and approach-roads.

---

Chap. III.

Scientific Processes and Operations.

1969. Scientific processes and operations include the master-operations of gardening as an art of culture. These operations are all mechanical; but some depend, for their beneficial result, on chemical changes, as in the preparation of composts and manures; others depend on the prevention of chemical changes, as in the preserving and keeping of fruits and roots; some on imitations of climates, as in the management of hot-houses; but the greater number are dependent on the laws of vegetable life, as in the operations of propagating, rearing, accelerating, and retarding vegetables. Other processes to be treated of are of a mixed nature, and some depend on the laws of animal life, as in the operations for destroying vermin and insects.

Sect. I. Preparation of fermenting Substances for Hot-beds, Manures, and Composts.

1970. The fermenting substances used in forming hot-beds are stable litter or dung in a recent or fresh state, tanner’s bark, leaves of trees, grass, and the herbaceous parts of plants generally.
1971. Stable-dung is in the most general use for forming hot-beds, which are masses of this dung after it has undergone its most violent fermentation. These masses are generally in the form of solid parallelograms of magnitude proportioned to the frames which are to be placed on them, the degree of heat required, and the season of the year in which they are formed.

1972. Tanners' bark is only preferred to dung because the substance which undergoes the process of putrid fermentation requires longer time to decay. Hence it is found useful in the bark-pits of hot-houses, as requiring to be seldom moved or renewed than dung, or any other known fermentable substance that can be procured in equal quantity.

1973. Leaves, and especially oak-leaves, come the nearest to bark, and have the additional advantage, that when perfectly rotten like dung, they form a rich mould or excellent manure; whereas rotten tanners' bark is found rather injurious than useful to vegetation, unless well mixed with lime and earth.

1974. Preparation of manures. The object of preparation in these three substances being to get rid of the violent heat which is produced when the fermentation is most powerful; it is obvious that preparation must consist in facilitating the process. For this purpose, a certain degree of moisture and air in the fermenting bodies are requisite; and hence the business of the gardener is to turn them over frequently, and apply water when the process appears impeded for want of it, and exclude rain when it seems chilled and impeded by too much water. Recent stable-dung generally requires to lie a month in ridges or beds, and be turned over in that time thrice before it is fit for cucumber-beds of the common construction; but for M'Phail's hot-beds, or for linings, or for frames with moveable bottoms, three weeks, a fortnight, or less, will suffice; or no time at all need be given, but the dung formed at once into linings. Tan and leaves require in general a month; but much depends on the state of the weather, and the season of the year. Fermentation is always most rapid in summer; and if the materials are spread abroad during frost, it is totally impeded. In winter, the process of preparation generally goes on under cover from the weather, in the back sheds; which situation is also the best in summer, as full exposure to the sun and wind dries too much the exterior surface; but where sheds cannot be had, it will go on very well in the open air. A great deal of heat is undoubtedly lost in the process of fermentation; and some cultivators have recently devised plans to turn it to some account, by fermenting dung in vineries, which are just beginning to be forced, or in vaults under pine-pits or plant-stoves. The latter mode seems one of the best in point of economy, and is capable of being turned to considerable advantage where common dung-beds are extensively used; but the most economical plan of any seems to be that of employing only M'Phail's pits, or such as are constructed on similar principles.

1975. The formation of dung-beds is effected by first marking out the dimensions of the plan, which should be six inches wider on all sides than that of the frame to be placed over it, and then, by successive layers of dung laid on by the fork, raising it to the desired height, pressing it gently and equally throughout. In general, such beds are formed on a level surface; but Knight's mode (fig. 375.) is to form a surface of earth as a basis, which shall incline to the horizon to the extent of fifteen degrees; on this he forms the dung-bed to the same inclination; and, finally, the frame, when placed on such a bed, if, as is usual, it be deepest behind, will present its glass at an angle of twenty degrees instead of six or eight, which is undoubtedly of tremendous advantage in the winter season. This seems a very desirable improvement where light is an object, which it must be, in a high degree, in the case of the culture of cucumbers and melons, as well as in forcing flowers.
